The results of the examination of 16,524 teachers in the Province of Quebec, with the exception of the City of Montreal, are shown in Table 1.

It is apparent that tuberculosis was twice as prevalent among religious teachers as it was among the lay teachers, even though most of the religious congregations have re-

quired, for the past few years, an x-ray examination of the chest from all applicants for admission to their groups.

In the City of Montreal, the results of examination for tuberculosis do not show the same trend. According to Dr. Laberge, the report was not complete for the religious teachers. The data from the Catholic School Commission are summarized in Table 2. The Protestant School Commission reported 1533 teachers x-rayed, only 1 of whom was rejected.

* * *

During August, 1939, an act passed by the Senate and General Assembly of New Jersey provided that the board of Education of every school district should periodically deter-

mine the presence or absence of active tuberculosis in any or all pupils in public schools. The rules and regulations for complying with this were to be made by the State Board of Education. Any pupil found with active tuberculosis was to be excluded from school until the disease was no longer communicable. Employees (which include teachers) of boards of education were required to have a physical examination by the provisions of a similar act passed at the same time. The State Board of Education was to determine the scope of such an examination.

The State Board of Education on May 11, 1940, ruled that all pupils of grades nine, ten, eleven and twelve and all special students enrolled in high school should be listed or

examined annually, as early as possible in each school year. For employees the board ruled that the examination was to be limited to determination of the presence or absence of tuberculosis.

This legislation was the climax of a long-term program of health education in homes, schools and community groups in New Jersey. Parents, children and school personnel were ready for the step when it was taken so there was no serious opposition in any county. The examinations themselves were used as an educational demonstration, and great care was taken to prepare pupils for them. It is now recommended that discussion with pupils should follow the testing. Answering students' questions and explaining the results in classrooms or individually will do much to give the procedure meaning.

X-ray examinations of the students who were positive reactors, and of a few students who were not tuberculin tested, revealed 343 cases of reinfection type tuberculosis or approximately 2 per 1000. Of the 2772 teachers examined, 67, or 2.4 per cent, had reinfection tuberculosis. Of these, 31 were classified as stable.

Reports on the disposition of reinfection type tuberculosis were incomplete. However, 23 patients were hospitalized, 21 were excluded from schools, 2 died shortly after examination and 40 students and employees were permitted to return to school under medical supervision with periodic x-ray examination.

Out of 195,130 students in New Jersey schools during 1941-1942, 19.9 per cent were positive reactors to the tuberculin test. Of 59,736 who were tested for the first time, 13.8 per cent were positive reactors. Retests of 99,964 students who were negative reactors in previous years yielded 10.7 per cent positive reactors. This group is highly significant from the standpoint of epidemiologic control. Its members have been recently in contact with an infection source. The prevailing infection rate in the school population therefore is slightly less than 20 per cent. Among teacher and employee group 39.7 per cent were positive reactors. Other significant chest, heart and orthopedic conditions were revealed by the school tuberculin testing and x-raying program. — Reprinted from *Tuberculosis Abstracts* (September, 1944).

BOOK REVIEW

A Catalogue of the Medieval and Renaissance Manuscripts in the Boston Medical Library. Compiled by James F. Ballard, director, Boston Medical Library. Sm. fol., 246 pp. Boston: privately printed, 1944.

The first impression in looking through the Boston Medical Library's new catalogue of incunabula and early manuscripts is that the volume has been planned — as every catalogue should be planned — to contain everything that

material with tiny knots accurately placed on small pieces of tissue was employed. These, of course, are the same criteria that Halsted set up for success with silk over fifty years ago.

Another defect of catgut was brought to light last year, when Dunham and Jenkins^{4, 5} showed that the tubing fluids with which most forms of catgut are impregnated contain highly irritating substances, which delay the process of repair.

A large dealer in surgical supplies has recently stated that the sales of silk and cotton for surgical use are rising by leaps and bounds and that the sale of catgut is stationary. Because of the fact that much of the silk and cotton for surgical use is bought through department stores, this statement assumes great significance. Of course, the manufacturers of catgut are improving their product, and catgut has a place in surgery, even in the work of those who are most enthusiastic in the use of nonabsorbable material. Such operations as those for hemorrhoids and for various types of gross infection will continue to need catgut, perhaps forever. Also, nonabsorbable sutures should never be buried in long strands, which means, for example, that the continuous suture used in the first layer for repair of the peritoneum should be made of catgut.

Any surgeon worthy of the profession should pride himself on his manual dexterity, and any busy surgeon with average dexterity, provided he is willing to devote a little care and thought, can quickly learn to use fine silk or fine cotton. The time may well be approaching when the use of catgut in routine operations will be the mark of a habit-bound surgeon.

MASSACHUSETTS MEDICAL SOCIETY

DEATHS

BLANCHETTE — William H. Blanchette, M.D., of Fall River, died August 1. He was in his seventy-second year.

Dr. Blanchette received his degree from Baltimore Medical College in 1896. He was a member of the American Medical Association.

HEAVEY — Thomas J. Heavey, M.D., of Med August 7. He was in his fifty-ninth year.

Dr. Heavey received his degree from the Middlesex School of Medicine, Waltham, in 1922. He was a member of the American Medical Association.

KICKHAM — Edward L. Kickham, M.D., of Boston died August 10. He was in his forty-ninth year.

Dr. Kickham received his degree from Tufts Medical School in 1923. He was a member of the medical and gynecologic staff of the Carney Hospital and St. Beth's Hospital, having been associated with the former in 1924 and with the latter since 1930. He had been in gynecology at Tufts College Medical School since 1924. He was a fellow of the American College of Surgeons, a member of the American Medical Association, the American Board of Obstetrics and Gynecology, and the Boston Obstetrical Society. He was treasurer of St. Luke's Church, Boston.

His widow, two brothers and a sister survive.

WAR ACTIVITIES

INDUSTRIAL HYGIENE

CHLORINE GAS HAZARDS IN ALUMINUM FOUNDRIES

The chlorine hazards in aluminum foundries have shown by a study made in California to be threefold:

Aluminum readily combines with the oxygen in air, releasing hydrogen gas, which collects in the interstices or porosities of aluminum in the melting pot. This is generally removed by passing chlorine through molten metal so that the hydrogen combines with chlorine to form hydrochloric acid. The excess chlorine discharged into the atmosphere above the melting unless removed by an exhaust hood, but the hood must be properly designed, or only a portion of the gas is removed.

The chlorine gas is introduced into the bottom of the melting pot by pipes connected to the tanks by lengths of rubber hose. These pipes may become clogged as the chlorine tanks are moved from pot to pot. As full tank pressure may exceed 100 pounds per square inch the rubber hose may leak or burst. Moreover, a chlorine tank may burst from overheating or from being tipped over, causing a fatality.

Gas burners under the melting pot are frequently vented, so that carbon monoxide concentrations may be as high as 50 to 75 parts per million and, as phosgene is readily formed from a combination of carbon monoxide and chlorine, there is danger of both carbon monoxide and phosgene poisoning.

Proper protection of the workmen requires a rather complicated system of control, consisting of venting of gas-burning devices, as well as much greater supervision of the method in which chlorine is handled. — Reprinted from *Industrial Hygiene News Letter* (July, 1944).

MISCELLANY

NOTE

The Hercules Powder Company has inaugurated educational tours to acquaint local physicians with working conditions to which their patients may be exposed. The first tour was made in Mansfield and attended by local physicians, representatives of the Massachusetts Division of Occupational Hygiene and the Committee on Industrial Health of the Massachusetts Medical Society.

TUBERCULOSIS IN SCHOOLS

The protection and education of children is universally conceded to be one of the primary functions of the modern state. In the realm of public health, especially that part which concerns itself with the control of tuberculosis, this

CHRONIC LATENT HEPATITIS FOLLOWING CATARRHAL JAUNDICE*

MARK D. ALTSCHULE, M.D.,† AND D. ROURKE GILLIGAN, M.D.‡

BOSTON

THERE are now available in the literature records of the persistence of icterus,¹⁻⁸ as well as reports describing increased plasma bilirubin and decreased bilirubin excretory function⁵⁻⁹ in some patients who years previously had had an attack of catarrhal jaundice. Chronic gastrointestinal complaints⁵⁻⁹ and chronic hepatic enlargement⁵⁻⁸ have also been reported as sequelae of acute catarrhal jaundice. The present report of laboratory and clinical studies made in an unselected series of 36 persons who had had catarrhal jaundice one to twenty-nine years previously similarly demonstrates in some cases the persistence for years of certain evidences of hepatic dysfunction and affords information concerning the frequency of abnormal findings. This study was thought to be particularly pertinent at the present time because of the large number of cases of catarrhal jaundice in the armed forces of the present war; the incidence of the disorder in the War of 1812, the American Civil War, the Franco-Prussian War and World War I was similarly high. There is no complete accord in the interpretation of the clinical significance of so-called "chronic latent hepatitis" following catarrhal jaundice; the present study adds information bearing on this problem.

MATERIAL AND METHODS

The group studied was made up almost entirely of members of this hospital staff, students of the Harvard Medical School and of Harvard College and subjects who had been patients in this hospital at an earlier date when they had an attack of catarrhal jaundice. All these subjects had been observed during their episodes of icterus by competent physicians, including physicians on the staff of this hospital and in the Department of Hygiene of Harvard University. When actual hospital or physicians' records were not available, the symp-

toms and signs and the physician's diagnosis at the time of the attack were reviewed with the subject. The latter were, with one exception, scientists, technicians or medical students.

The bilirubin measurements were made by the method of Malloy and Evelyn, employing the

FIGURE 1. Plasma Bilirubin Levels in Persons with and without a History of Catarrhal Jaundice.

Evelyn photoelectric colorimeter.¹⁰ During the study the plasma bilirubin concentration was also measured in 36 normal persons with no history of hepatic disease and no signs of any visceral disorder. These subjects had plasma bilirubin levels ranging from 0.08 to 0.82 mg. per 100 cc., with an average of 0.31 mg., 32 subjects having values of 0.6 mg. or less (Fig. 1). These findings are essentially the same as those reported for normal subjects by Malloy and Evelyn,¹⁰ using the same method, and by Kornberg.⁸

‡Associate in medical research, Beth Israel Hospital; research associate, Harvard Medical School.

one needs and nothing more, in itself a bibliographical feat of high order. Its annotations, for instance, are a model of scholarly discrimination — brief, to the point, and present only when needed to emphasize information of importance. In addition to its seven hundred and twenty-six entries, there are three concordances and five indices. Thus it has been made not only a lean volume, but a well-rounded one.

The collection has as its purpose the gathering of such manuscripts and early printed books as might have been brought together in a fifteenth-century physician's library. Such, in fact, was the original aim of Dr. William Norton Bullard, whose collection, first through loan and then through bequest, forms the foundation upon which the library's collection rests. To his books have since been added purchases from the Bullard, the Godfrey M. Hyams and the John Warren funds, as well as from the library's general resources, with the result that the collection now totals fifty-two medieval and renaissance manuscripts, and six hundred and seventy-four early printed books.

As is to be expected, the majority of these are of medical interest. But, in rounding out the collection, the director has taken into consideration the fact that a physician of the fifteenth century no doubt had minor interests and hobbies, which would have brought books on other subjects to his shelves. For this reason, in Mr. Ballard's excellent subject-index, one finds occasional and intriguingly nonmedical books on architecture, geology, gambling, hunting, orations, inventions and canon law.

A library reproducing such a physician's interests, it seems, is not a hypothetical matter. As pointed out in Dr. Henry R. Viets's scholarly introduction to the catalogue, the manuscript collection follows closely the titles known to have been in the library of Giammatteo Ferrari da Gradi, who was professor of medicine at the University of Pavia from 1432 to 1472, as also the medical books in the scientific library brought together by Cardinal Nicolaus of Cues prior to 1464. Similarly, the fifteenth-century printed books run parallel to those known to have been in the collections of contemporary physicians, such as Hieronymus Münzer, Hartmann Schedel, Ulrich Ellenbog and Nicolaus Pol. In fact, the library actually has a number of books from Münzer's collection.

Through the medical incunabula upon the Library's shelves, it is possible to understand the status of medical science at the time of the invention of printing. "when the impounded waters of culture were let loose." Through the early manuscripts here assembled, it is possible to reconstruct the historical background upon which medical science then rested.

Collectanea Medica, a manuscript written by various physicians within the two-hundred-year period from 1250 to 1450, treats of a fascinating combination of subjects — eye and skin diseases, corns, "palsey," measles, gout, laryngitis, food and drink in relation to health and so forth. In addition, it includes a fourteenth-century prayer, written about 1350, to be pronounced by a physician when administering a remedy; and also a formula for extracting blue coloring from lapis lazuli which, interestingly enough, may have some bearing on the quality of the blue used in the beautifully illuminated borders and initial letters of the period. Another *Collectanea Medica*, written about 1450, contains treatises on the detection of disease, the plague, and the effects of the zodiac on blood-letting. A *Register Simplicium*, a manuscript of special interest, written in Austria in 1477, contains a long inventory of medieval drugs and materia medica.

On the opening page of the incunabula section of the catalogue there is an entry for the 1471 Jensen edition of Abulcasis. Bound with the library's copy of this work is Nicolaus Salernitanus's *Antidotarium* of the same press and year. Farther on in the text are noted later editions of Mesue's *Opera Medicinalia*, first printed in 1471, and of Pliny's *Historia Naturalis*, issued in 1469 and again in 1470. And prior to the Pliny came the *De Sermonum Proprietate* of Rabanus Maurus, undated but assigned to a Strassburg press before July 20, 1467. The last not only has its honored place upon the library's shelves, but it heads the list in Osler's *Incunabula Medica*, as the first "medical" book known to have been set in type. Thus, exclusive of single-leaf prints, the catalogue accounts for a half dozen of the first medical items

known to have been circulated in printed form. And among the early broadsides, the library is fortunate in possessing the rare third *Almanac* in German, a blood-letting calendar, assigned to the Zainer press at Augsburg about 1469-1470. Although part of its second column is lacking, the only other copy of the *Almanac* that is known (in Munich) has the second column intact, but lacks part of the first. Thus, the two copies together provide the complete text.

Among the books of anatomical interest are Peygh's *Compendium Philosophiae Naturalis*, the first printed anatomical treatise with illustrations; and Brunschwig's *Das Buch der Chirurgia*, printed at Strassburg by Grüninger in 1497. In the copy described, new matter has been added, including a brief tract on anatomy and a woodcut diagram of a skeleton. In view of the questions involved in the making up of this variable work, it is worthy of note that the library's copy — perfect, uncolored and in prime condition — is identified in Mr. Ballard's note as follows: "The first impression of the first edition [of *Das Buch der Chirurgia*] with the first printing of the added *Anatomia* as described by Sudhof Arch.f.d.Gesch.d.Med., Lpz., 1907-1908, 1:41. With 45 large woodcuts printed from 18 different combined blocks 13 small woodcut illustrations, and the full-page woodcut of the skeleton for the *Anatomia* adapted from the Helian broadside of 1493." Of even greater rarity is a broadside probably contemporary with the woodcut accompanying the *Anatomia* [early 1498?]. This represents a skeleton drawn with much artistic feeling, and engraved on copper by Zoot Andrea — a broadside of which only two other copies are known, and those both in Paris.

Six books were not registered as in the country in 1940, when the second census of incunabula in North American libraries was published. The Catalogue thus adds to our records the German *Almanac* already mentioned, a German edition of the *Ruralia Commoda* of Petrus de Crescentiis, the *Recollectae super Physica Aristotelis* of Galetanus de Thienis, the *Lunarium* of Bernardus de Granollachs, a *Tractat contra Pestem*, attributed to Heinrich Louffenberg, and the *Prothonotariomastix* of Paulus de Middelburgo.

By the cleverly economical phrases, "not in Osler" and "not in Klebs," used advisedly with a few entries, Mr. Ballard has given passing emphasis to a score or so of titles whose interest to medical science has made them in his opinion worthy of inclusion. Among them he notes the important *Bull on Burials*, issued by Bonifacius VIII, which, in its condemnation of the dismemberment of bodies of the dead, was for a time, until its re-interpretation, accepted as opposed to dissection and hence to the acquiring of direct anatomical knowledge.

In providing a subject-index for the volume, Mr. Ballard has made a very vital and important contribution to the study of incunabula. For early printed books, like other books, were originally published because of the timeliness of their subject interest. Various bibliographers, Dr. Osler foremost among them, have within fairly recent years segregated medical incunabula. Dr. Klebs has contributed still more to the classifying of incunabula by enlarging his survey of medical incunabula to include other sciences. But Mr. Ballard in his subject-index has broken down the broad classification into the specialized interests of the individual books. In other words, he has analyzed his incunabula just as modern books are indexed, thus making a contribution both to the study of incunabula and to the history of medicine. Here, in the catalogue of a collection brought together for the purpose of reproducing a fifteenth-century physician's library, is a subject-index of some two hundred entries. Thus the catalogue gives knowledge not only of physicians' books but of their contents as well.

It is a pleasure to find that publication of the catalogue has come at a time when Mr. James F. Ballard, director of the Boston Medical Library, has completed fifty years of service. The volume thus stands most fittingly as the culmination of his long years of scholarly labor.

It has been issued in an edition of four hundred copies, planned in an appropriate, clearcut format by Dr. Viets, the librarian, and printed by the George Banta Publishing Company of Menasha, Wisconsin.

(Notices on page xv)

ndice recover completely. The occurrence of ite or subacute yellow atrophy followed by uth or the development of clinical manifestations chronic cirrhosis of the liver has been observed occasional cases immediately after or shortly er an attack of infectious hepatitis; these imediate sequelae will not be discussed. That jaunde may be persistent in some patients following arrhal jaundice has also been stated previously a number of authors.¹⁻⁸ Studies of the plasma bilirubin concentration confirming this statement ive been recorded.⁵⁻⁸ In addition, impairment of ilirubin excretion after administration of bilirubin as been described by Soffer and Paulson,⁹ Kalk,^{5, 6} ad Kornberg.⁸ The results of the present study onfirm these earlier findings. Our observation at abnormally high plasma bilirubin values persted for years in 25 per cent of this series indicates higher incidence of chronic mild impairment of hepatic function following catarrhal jaundice than as been generally believed to exist. The fact hat impairment of bilirubin excretion is not inrequently demonstrated by the bilirubin-excretion est following catarrhal jaundice, even when there is no chronic hyperbilirubinemia,^{8, 9} indicates that the incidence of chronic mild impairment of liver function is even higher than demonstrated by the 25 per cent incidence of chronic hyperbilirubinemia in our subjects. This concept is supported by the observation that the distribution of the plasma bilirubin values of the 27 patients who had had catarrhal jaundice but had bilirubin values within the normal range includes an abnormally large number of values in the high normal range (Fig. 1).

The significance of the persistently abnormal hepatic function after infectious hepatitis is not clear. A wide variety of vague chronic complaints, including dyspepsia, abdominal fullness, upper abdominal discomfort, anorexia, heartburn, fatigue and belching, are described in such patients by Kalk,^{5, 6} Polack,⁷ Kornberg⁸ and, less emphatically, by Soffer and Paulson.⁹ Kalk⁶ also records complaints of a bad taste in the mouth, a feeling of tension, loss of ambition, headache, strong thirst, a craving for sweets and an aversion to alcohol and fat. In our own cases the icterus, when persistent, was not associated with chronic gastrointestinal complaints or a greater than normal incidence of acute gastrointestinal upsets; evidence of impaired utilization of vitamin A was, however, present in 2 cases. Enlargement of the liver, as well as that of the spleen in 1 case, was not associated with symptoms in these cases, although other authors⁵⁻⁸ described hepatic enlargement in many of their patients with a variety of gastrointestinal complaints following catarrhal jaundice. It should be emphasized that our subjects were unselected. Thirty-four of them came to our attention as a result of our own efforts to secure subjects recovered from catarrhal jaundice and not because they sought medical advj 2 cases, the subjects required

medical attention for symptoms unrelated to hepatic dysfunction.

The hepatic-histopathologic changes responsible for the evidences of retention of bilirubin in these patients are unknown. The prognosis also is not clear. The occasional occurrence of cirrhosis of the liver years after the apparent complete recovery from what appears to have been catarrhal jaundice has been noted by some clinicians,¹³ but, this must be an extremely infrequent occurrence if one is to judge from the relative frequencies of catarrhal jaundice and of hepatic cirrhosis.

It is concluded, therefore, that the chronic latent hepatitis that often follows apparent recovery from catarrhal jaundice is usually benign and unassociated with symptoms and is therefore not clinically significant; in rare cases it is the fore-runner of the clinical syndrome cirrhosis of the liver.

SUMMARY AND CONCLUSIONS

Studies of 36 persons who had had attacks of catarrhal jaundice one to twenty-nine years previously revealed hyperbilirubinemia in 25 per cent. It is probable that the incidence of impairment of liver function was even higher, since the distribution of plasma bilirubin values revealed an abnormally large number in the high normal range. Nine subjects in the entire group had palpable livers and 1 a palpable spleen. The chronic latent liver disorder revealed by this study was not accompanied by symptoms and did not appear to be progressive. It is concluded that a mild, benign form of chronic hepatitis is frequent after catarrhal jaundice.

We are indebted to Drs. Arlie V. Bock and Andrew W. Contratto, of the Hygiene Department, Harvard University, and Drs. Lewis Dexter and Lewis W. Kane, of the Harvard Medical School, for their help in obtaining many of the subjects of this study.

OBSERVATIONS

Plasma bilirubin levels. The plasma bilirubin concentrations ranged between 0.23 and 3.01 mg. per 100 cc. in the 36 patients who had recovered from infectious hepatitis; 16 had values above 0.60 mg. and 9, values above 0.82 mg. — that is, higher than any value found in the group of 36 normal subjects (Fig. 1). Four patients had had two or three attacks of jaundice. There was no relation between the concentration of plasma bilirubin and

Symptoms. Except for one patient with active peptic ulcer, another with active colitis and a third with a history of irritable colon many years previous to this study, none of the patients, icteric or not, had any chronic gastrointestinal complaints or any unusual number of gastrointestinal upsets. None showed lack of stamina; many of the subjects were or had been college athletes, including the one with the highest plasma bilirubin found, — namely, 3.01 mg. per 100 cc., — who was at the time of

*Distance below costal margin

†Skin also icteric.

‡Spleen also palpable

§According to the patient's history, he had often had plasma bilirubin levels as high as 4.0 mg per 100 cc

the occurrence of multiple attacks, nor was there any correlation of the former with the elapsed time between the attack and the present study (Table 1). The scleras appeared slightly icteric in 7 patients, all of whom had plasma bilirubin levels above 0.9 mg. per 100 cc. A yellowish tinge to the skin was present in 2 patients.

Hepatic and splenic enlargement. The liver was palpable 1 or 2 cm. below the costal margin in 9 patients, only 5 of whom had plasma bilirubin levels above the normal range. The spleen was felt in only 1 case, in which the plasma bilirubin concentration was 1.32 mg. per 100 cc.

study a member of the Harvard crew. Two of the group, whose plasma bilirubin values were 0.89 and 1.98 mg., respectively, fifteen and twenty-one years after an attack of infectious hepatitis, had the skin changes of moderately severe vitamin A deficiency in spite of the ingestion of adequate diets.

DISCUSSION

The disorder known as catarrhal jaundice has been shown to be a form of hepatitis^{11, 12} apparently consequent to infection, although the causative agent has not been identified. It has been generally believed that almost all patients with

jaundice recover completely. The occurrence of acute or subacute yellow atrophy followed by either the development of clinical manifestations of chronic cirrhosis of the liver has been observed in occasional cases immediately after or shortly after an attack of infectious hepatitis; these immediate sequelae will not be discussed. That jaundice may be persistent in some patients following catarrhal jaundice has also been stated previously by a number of authors.¹⁻⁸ Studies of the plasma bilirubin concentration confirming this statement have been recorded.⁵⁻⁸ In addition, impairment of bilirubin excretion after administration of bilirubin has been described by Soffer and Paulson,⁹ Kalk,^{5, 6} and Kornberg.⁸ The results of the present study confirm these earlier findings. Our observation that abnormally high plasma bilirubin values persisted for years in 25 per cent of this series indicates a higher incidence of chronic mild impairment of hepatic function following catarrhal jaundice than has been generally believed to exist. The fact that impairment of bilirubin excretion is not infrequently demonstrated by the bilirubin-excretion test following catarrhal jaundice, even when there is no chronic hyperbilirubinemia,^{8, 9} indicates that the incidence of chronic mild impairment of liver function is even higher than demonstrated by the 25 per cent incidence of chronic hyperbilirubinemia in our subjects. This concept is supported by the observation that the distribution of the plasma bilirubin values of the 27 patients who had had catarrhal jaundice but had bilirubin values within the normal range includes an abnormally large number of values in the high normal range (Fig. 1).

The significance of the persistently abnormal hepatic function after infectious hepatitis is not clear. A wide variety of vague chronic complaints, including dyspepsia, abdominal fullness, upper abdominal discomfort, anorexia, heartburn, fatigue and belching, are described in such patients by Kalk,^{5, 6} Polack,⁷ Kornberg⁸ and, less emphatically, by Soffer and Paulson.⁹ Kalk⁶ also records complaints of a bad taste in the mouth, a feeling of tension, loss of ambition, headache, strong thirst, a craving for sweets and an aversion to alcohol and fat. In our own cases the icterus, when persistent, was not associated with chronic gastrointestinal complaints or a greater than normal incidence of acute gastrointestinal upsets; evidence of impaired utilization of vitamin A was, however, present in 2 cases. Enlargement of the liver, as well as that of the spleen in 1 case, was not associated with symptoms in these cases, although other authors⁵⁻⁸ described hepatic enlargement in many of their patients with a variety of gastrointestinal complaints following catarrhal jaundice. It should be emphasized that our subjects were unselected. Thirty-four of them came to our attention as a result of our own efforts to secure subjects recovered from catarrhal jaundice and not because they sought medical advice. In 2 cases, the subjects required

medical attention for symptoms unrelated to hepatic dysfunction.

The hepatic-histopathologic changes responsible for the evidences of retention of bilirubin in these patients are unknown. The prognosis also is not clear. The occasional occurrence of cirrhosis of the liver years after the apparent complete recovery from what appears to have been catarrhal jaundice has been noted by some clinicians,¹³ but, this must be an extremely infrequent occurrence if one is to judge from the relative frequencies of catarrhal jaundice and of hepatic cirrhosis.

It is concluded, therefore, that the chronic latent hepatitis that often follows apparent recovery from catarrhal jaundice is usually benign and unassociated with symptoms and is therefore not clinically significant; in rare cases it is the forerunner of the clinical syndrome cirrhosis of the liver.

SUMMARY AND CONCLUSIONS

Studies of 36 persons who had had attacks of catarrhal jaundice one to twenty-nine years previously revealed hyperbilirubinemia in 25 per cent. It is probable that the incidence of impairment of liver function was even higher, since the distribution of plasma bilirubin values revealed an abnormally large number in the high normal range. Nine subjects in the entire group had palpable livers and 1 a palpable spleen. The chronic latent liver disorder revealed by this study was not accompanied by symptoms and did not appear to be progressive. It is concluded that a mild, benign form of chronic hepatitis is frequent after catarrhal jaundice.

We are indebted to Drs. Arlie V. Bock and Andrew W. Contratto, of the Hygiene Department, Harvard University, and Drs. Lewis Dexter and Lewis W. Kane, of the Harvard Medical School, for their help in obtaining many of the subjects of this study.

DISLOCATION OF THE KNEE JOINT*

A Report of Two Cases

JAMES WARREN SEVER, M.D.†

BOSTON

THIS is a report of 2 cases of dislocation of the knee joint—one an anterior dislocation of the knee and the other a compound posterior medial dislocation.

CASE 1. The patient, a 47-year-old carpenter, was admitted to the Cambridge Hospital on June 29, 1942, shortly after falling 15 feet from a ladder. His right leg was in a Thomas splint, which had been applied by the police. Inspection showed an anterior dislocation of the knee (Fig. 1), with the distal end of the femur causing great pressure on the skin in the popliteal space. An anesthetic was immediately given, and the dislocation was reduced on a Bell

The patient was discharged on August 2, with the leg in the bivalved cast, which was removed on September 1. Following this he began to bear weight on the leg, first with crutches and then with a cane, and got about very well. During this period he received physiotherapy for the development of the quadriceps muscle. On September 15, it was noted that he was walking with a marked toe drop and considerable weakness in the peroneal and tibial groups as well as in the dorsal flexors of the foot. As a result of this condition, a short caliper splint was applied to prevent the drop, with marked improvement in walking. The patient continued his physiotherapy. By October he had considerable improvement, and in November the strength of the dorsal flexors, tibials and peroneals had in-

FIGURE 1. Roentgenograms Showing an Anterior Dislocation of the Right Knee (Case 1).

table without great difficulty. In effecting the reduction a heavy canvas strap was placed around the back of the thigh just above the knee, and traction was applied on the lower leg in the line of deformity, with slight flexion at the same time. Following this, a plaster spica was applied from the toes, with the knee flexed at an angle of 20 or 25°. A check-up x-ray film showed no evidence of fracture and complete reduction. Before the dislocation was reduced, there was some obvious interference with the circulation in the toes, but after reduction the circulation was completely restored. The patient wore the spica from June 29 to July 13, when a new cast was applied from the toes to the groin. At that time there was no swelling of the knee joint, the skin was in good condition, and circulation was satisfactory.

On July 29, the cast was bivalved and the leg was inspected. There was good muscle strength, no swelling of the knee and some active motion in the knee joint. There was no apparent lack of stability, but there was still some evidence of ecchymosis about the knee.

almost to normal. He was still wearing his brace, but in the latter part of November he had improved to such an extent that it was removed. At that time he had excellent strength in the quadriceps and had returned to his work. When last seen on February 5, 1943, the knee showed no evidence of pain, discomfort or instability. There was no evidence of any injury to the semilunar cartilages, nor was there evidence of instability due to injury of the crucial ligaments, that is, undue mobility of the tibia on the femur with the leg extended or the knee flexed. The knee could be fully extended and could be flexed 10° beyond a right angle, and the joint was in excellent weight-bearing position. Full power in the dorsal flexors and other muscles of the lower leg had been recovered, and there was no atrophy.

CASE 2† The patient, a 39-year-old telegraph operator, was struck from behind by an automobile on March 14, 1942, suffering a posterior medial dislocation of the left knee (Fig. 2), compounded into the popliteal space through a 7-cm. wound, with periosteal stripping of the lower end of the femur (Fig. 2), as well as a compound comminuted fracture of the upper third of both bones of the lower right leg. He

†I am indebted to Dr. G. Guy Bailey, Jr., for permission to report this case.

treated for 8 weeks in a plaster cast after reduction of dislocation and repair of the compound wound, and so the dislocation was concerned made a perfect recovery. It took considerably longer to repair the condition of the right leg. It was 4 weeks after removal of the cast before the patient attempted weight bearing on the left leg. With physiotherapy, he made a perfect recovery so far as the dislocation was concerned, and eventually the comminuted fracture of the other leg healed, so that he was able to resume work.

At examination on February 12, 1944, the left leg was straight, with excellent muscle strength and full extension of the knee joint, which could be flexed 10° beyond a right

FIGURE 2. Roentgenogram Showing a Posteromedial Dislocation of the Left Knee (Case 2).

angle. There was slight lateral instability or increased motion in the joint. There was no evidence of any injury to the semilunar cartilages as manifested by swelling, locking or instability, and no pain or discomfort. Furthermore, there was no evidence of instability due to injury to the crucial ligaments. In spite of the extensive injury, no injury to the nerves or vessels had been sustained.

DISCUSSION

In the literature on dislocations of the knee,¹⁻⁷ it is emphasized by the various authors that there is total destruction of various ligaments in and about the knee joint. Injuries to the nerves, particularly the peroneal nerve,¹ due to stretching, is not infrequent. In one case the sciatic nerve was completely severed. Occasional cases of thrombosis of the post-tibial as well as the popliteal artery have been reported,^{1,2} these cases requiring amputation.³ The nerve injury, except for the cases showing complete section, usually healed, as was true in Case 1 of this report.

In discussing dislocations of the knee joints, one speaks in terms of displacement of the lower leg; that is, an anterior dislocation means a forward displacement of the tibia on the femur and so forth. This condition is extremely rare, and Ritter⁴ reports that in 23,000 accident cases in the Reconstruction Hospital in New York, dislocation of the knee joint occurred in only 1 case, and that this was not a complete dislocation. He adds that at the New York Post-Graduate Hospital there were only 3 cases in a long period of years. All the authors speak of the comparative ease of reduction, which, of course, is to be expected considering that all the structures about the knee joint have been torn. In one or two reports open operations have been done to reduce the dislocations, but this does not seem indicated.⁵ Most authors believe that fixation for six or eight weeks, later combined with physiotherapy and sometimes with a knee cage splint, is a better form of treatment. Others believe that passive motions begin in ten days, with early weight bearing at fourteen days, is the proper method. It seems wiser to me to wait until the structures about the knee joint have undergone repair before abusing them by early motion and weight bearing.

The most frequent type of dislocation about the knee is the anterior one, which occurred in 40 per cent of the cases reported. This takes place when the knee is in full extension. Posterior dislocations occurred in 20 per cent and result when the knee is in flexion. Lateral dislocations occurred in 20 per cent, and medial ones in 7 per cent. Which of the two latter occurs of course depends on whether the force is applied from the inner or the outer side of the leg. It is interesting to note that in many cases, even with such a severe injury, a satisfactory, stable and excellently functioning knee joint has resulted.

SUMMARY

Two cases of dislocation of the knee joint are reported, and the pertinent literature is discussed.

BOSTON MEDICAL LIBRARY

Report of the President*

IT IS the privilege of our librarian, Dr. Viets, to give an account of our professional activities, of the state of our collections of books, periodicals and memorabilia and of our services to the medical and lay public. The duty of the president is to make known to the fellows and friends of the Library its physical and financial condition, its needs, its projects and its hopes.

The year 1943, the second of our country's complete preoccupation with a desperate global war, has naturally found the Library striving to maintain its facilities and functions rather than to extend its undertakings in a way that would necessarily be incompatible with the war effort. We have not been hibernating, but our circulation and metabolism have suffered inevitable reduction, from which, when peace reigns again, we shall rally to renewed activity and wider usefulness.

There has been a net gain in our membership of twenty-eight. During the year eight fellows have died, as follows: Dr. Seth F. Arnold, Dr. Charles S. Butler, Dr. C. Macfie Campbell, Dr. Isador H. Coriat, Dr. Charles C. Foster, Dr. Amos I. Hadley, Dr. George A. Leland and Dr. Halbert G. Stetson. The loyalty of many of these men who, though they had retired and probably no longer needed the Library, continued actively to support it merits a word of appreciation. Dr. Foster, for instance, did not let his eighty-seven years serve as a reason for resigning; perhaps he continued to enjoy browsing in the stacks or passing a comfortable hour of reading in the Prince Room. We are proud to record that one hundred and fifty-nine of our members are in active service and that we have done what we could to acknowledge our debt to them by remitting their dues.

In my last annual report was recorded the decision of the Rationing Board to reduce our supply of fuel oil to a point incompatible with a continuance of our activities as a going concern, and our consequent contract with the Boston Edison Company to make suitable installations and supply steam for heating. This conversion was promptly and skillfully made, and the new system has been adequate and satisfactory, but it has resulted in an increase of operating expense due not only to the increased cost of service but also to the loss of \$1100 that we received annually by supplying heat under the old system to the Massachusetts Historical Society. We are grateful, however, that we are warmed and sheltered, and able to pursue our work with no more serious interruptions than practice air-raid alarms.

The financial statement and balance sheet have been examined and approved by highly responsible certified public accountants. Last year our income

from fellowship and membership dues was \$497 less than the year before; this year there has been a further decrease of \$411. Our income from investments, however, shows a gratifying increase of \$624, and our actual operating balance sheet shows a deficit considerably less than the \$1305 recorded a year ago. On the other hand, we have had to charge against capital approximately \$9500 to meet the cost of the conversion to steam heat and of structural alterations and renovations to improve the offices of the Massachusetts Medical Society and its organ, the *New England Journal of Medicine*, and of the *Journal of Bone and Joint Surgery*, which is the official publication of the American Orthopaedic Association. This money has been found in part by a loan secured from a commercial bank and in part by borrowing from the unexpended balance of our own restricted funds—a debt that of course must be repaid with the same fidelity as the bank loan. And mention of our financial debts cannot be dismissed without a reminder that our loan from the Massachusetts Medical Society, while somewhat reduced, still stands at \$19,000.

The corporation and friends of the Boston Medical Library must look more deeply into our affairs than merely to scrutinize the balance sheet of our current operations. Actuated by principles of honorable frugality, the trustees have made both ends meet by the most scrupulously careful budgeting. But the Library is in danger of stagnation unless its resources can be materially increased. Our house is in good condition, but it is unfinished. There is room for five additional tiers of steel stacks that were provided for in the original plans, and lacking which our accessions of books and periodicals are piled in the cellar and in passageways. The periodical room is a barnlike hall with the roughest sort of filing alcoves and furniture. Holmes Hall needs refitting and rearrangement to make it really adequate as a reading and delivery room. But more than anything we need improved service. Our director, Mr. Ballard, although he has done better than Ponce de León in his search for the mythical fountain, cannot be expected to carry his heavy burden indefinitely, and a young man of promise should be working by his side, absorbing his familiarity with the Library and its treasures and his skill in library administration—the fruit of fifty years' experience. Our research librarians and cataloguers should likewise have apprentices. A sum of \$100,000 would take care of the improvements in plant, and an additional income of \$10,000 per year would enable us to lead with authority in the plans already made to correlate and unite the various working collections of medical books in and around Boston in a truly co-operative and mutually helpful way. We

*Read at the annual meeting, March 7, 1944.

t search for and inspire generous donors to help with gifts and to remember us in their wills. In the decision of the trustees of a charitable institution that we recently approached that they must grant our request because we obviously had a constituency to whom we could look for support, we must convince public-spirited citizens that the offerings of physicians are rarely sufficient to enable them to make capital contributions.

There are cheerful things to record, as well as sad. The trustees were touched to be told by the executors of the will of the late Annie G. Farlow, widow of our former librarian and enthusiastic supporter, Dr. John W. Farlow, that she had made an unrestricted bequest to the Library of \$10,000 in memory of her husband. Dr. Farlow's avocation was the Library, and to it he gave without stint services more valuable than money. At his death he bequeathed \$10,000, which was applied to urgent needs. His widow paid for the installation of the elevator and has helped us in other ways, and now posthumously adds another to our reasons for gratitude. The Massachusetts Medical Society and the *Journal of Bone and Joint Surgery* have confirmed their alliance with us and have increased their contribution to our support in return for the enlarged space and improved facilities that we have been able to afford them. The Suffolk District

Medical Society has maintained its generous contribution, adding to the sum specifically due us for entertaining them. The James F. Ballard Publication Fund, which we started last year, has financed the publication of the *Catalogue of the Medieval and Renaissance Manuscripts and Incunabula in the Boston Medical Library*, which has been received with great approval by medical librarians and bibliophiles. It is our hope that this fund may receive constant additions, so that publications based on its treasures may be made by the Library from time to time.

As president I cannot close this brief report without paying tribute to the faithful service rendered by those responsible for the well-being of the Library. The trustees have attended the regular meetings of the Board and of standing committees in spite of exacting duties elsewhere. Of the executive officers, who receive no compensation, the secretary, the treasurer and the librarian must give much time to their work, especially the last, whose activity governs and regulates our whole endocrine system. Our director, Mr. Ballard, and the faithful group of research librarians and cataloguers continue the traditions of many years. They deserve the help and support of the corporation of the Boston Medical Library and of a wider public.

DAVID CHEEVER, *President*

MEDICAL PROGRESS

THE LATE EFFECTS OF TOTAL AND SUBTOTAL GASTRECTOMY*

FRANZ J. INGELFINGER, M.D.†

BOSTON

RESECTION of the human stomach, particularly of the distal half, has become a practical surgical procedure that carries a remarkably low mortality rate. In some clinics, gastric resections for malignant tumors are attended by a mortality rate of less than 10 per cent, whereas those carried out for benign lesions have a mortality risk of only 1 to 3 per cent.¹⁻⁶ It is therefore not surprising that gastrectomy is being performed with ever-increasing frequency, not only for gastric neoplasms but also in the treatment of peptic ulcers of the stomach, duodenum and jejunum.

In the case of cancer, gastric resection may have to be most extensive, sometimes total. In the case of ulcer, the amount of stomach removed varies with the operator and the particular problem presented by the patient, but many surgeons recommend that the gastric antrum and at

least two thirds of the stomach be removed, under the reasonable conviction that the chances of a recurrent ulcer are decreased by leaving a gastric remnant that has little or no capacity to form free hydrochloric acid.^{3, 6-9} In short, one purpose in undertaking a gastrectomy for ulcer is the suppression of the normal secretory functions of the stomach.

Can man live without a stomach or with a stomach whose functions are grossly impaired? The answer to this question has always been "Yes," but from time to time it is reported that life under such conditions is not invariably normal. In this review, recent evidence bearing on this problem is considered, for the present popularity of gastrectomy warrants an appraisal of any possible late effects that may follow total or subtotal removal of the stomach. The immediate postoperative complications are not discussed, nor does this review deal with the undoubted efficacy of gastrectomy in the treatment of gastric neoplasms and of

*From the Evans Memorial, Massachusetts Memorial Hospitals, and the Department of Medicine, Boston University School of Medicine.
†Assistant professor of medicine, Boston University School of Medicine.

many peptic ulcers. So far as possible, only those effects that can be directly ascribed to resection of gastric tissue are reviewed, but it is probable that some of the symptoms for which gastrectomy has been blamed have actually been caused by post-operative ulcer, gastritis or jejunitis. Allowance must also be made for the fact that many of the data presented by various authors have not had the benefit of a careful statistical analysis, as has been recommended by Hollander and Mage.¹⁰

CLINICAL OBSERVATIONS

Among those patients who have undergone gastrectomy, a clear majority find their mode of life unaffected by the fact that half or more of the stomach has been removed. On the other hand, many patients find it difficult to gain weight, some suffer from postcibal distress, and a few are subject to diarrhea. In a series of 104 patients with subtotal gastric resection, Church and Hinton¹¹ found that 47 per cent lost, 39 per cent gained and the remainder maintained their weight in a post-operative period that averaged nearly three years. Somewhat similar is the experience of Browne and McHardy,¹² who followed 30 gastrectomized patients for periods ranging from two to eleven years after operation and noted that 20 of these lost weight. Miller,⁵ reporting a series of 173 cases, states that the majority did not gain weight easily, but he records actual weight loss in less than 10 per cent. This figure is more in line with the results reported in earlier series.¹³⁻¹⁵

The value of statistical analysis is exemplified by a paper by Santy and Mallet-Guy.¹⁶ These authors divided their material according to the length of the postoperative period and showed that whereas 50 per cent of the patients followed for one to three years failed to regain their normal weight, only a few of the patients observed over longer intervals experienced difficulty in putting on weight. Furthermore, of the 50 per cent who failed to regain their normal weight, only one third — that is, 17 per cent of the whole group — failed to maintain their preoperative weight.

Total gastrectomy in young animals arrests growth and weight gain,^{17, 18} and even adult animals without stomachs may lose weight¹⁹ or require a higher dietary intake than does the normal animal.²⁰ In man, Farris, Ransom and Coller,²¹ and Joll and Adler²² indicate that maintenance of weight does not present a serious problem after total gastrectomy, but Rekers, Pack and Rhoads²³ observe that patients seldom return to their original weights after total removal of the stomach. It is interesting that appetite may be unimpaired after complete gastrectomy.^{22, 24}

The postcibal distress experienced by some gastrectomized patients follows a fairly typical pattern. Even while the patient is still at his meal, and although his appetite may not be assuaged, a marked

sensation of epigastric pressure, distention or fullness develops that prevents him from taking another morsel. Nausea may accompany the symptoms, and occasionally weakness, dizziness, perspiration and palpitation occur within an hour after the meal. To relieve his distress, the patient may belch, induce vomiting or assume certain positions that he has discovered to be effective in mitigating his symptoms. The incidence of a persistent postcibal symptom complex following subtotal or total gastrectomy is probably about 10 per cent,^{11, 13-15} although reports on this point vary. A rather dark picture is drawn by Jordan,⁵ who found that abdominal symptoms occurred post-operatively in 13 of 20 patients operated on for severe duodenal ulcer, in 18 of 41 operated on for bleeding ulcer and in 8 of 12 operated on for stomal ulcer. This series, however, includes ulcer recurrences and other complications. In discussing Jordan's paper, Mateer²⁵ states that after subtotal gastrectomy 14 per cent of his patients suffered from mild and 4 per cent from severe symptoms that could not be ascribed to ulcer recurrences. Of Browne and McHardy's¹² 30 patients, 16 complained of dyspepsia. On the other hand, only 4 of the 74 patients followed by Vitkin²⁷ had epigastric complaints. Three fourths of 113 patients observed by Weissenborn²⁸ were absolutely free of symptoms, about 20 per cent had mild distress, and only 5 per cent had symptoms that interfered with their daily routines. In general, failure to gain weight is particularly noticeable in the group of patients complaining of gastrointestinal symptoms, but the converse does not hold; many underweight patients are completely symptom free.

Frank diarrhea with cramps has been reported as a sequel to gastrectomy,^{12, 29} but it is not very frequent. Many patients, however, find that their stools are soft or even mushy following the operation.

It is emphasized by many writers that the symptoms that can be ascribed to total or subtotal gastrectomy tend to decrease in frequency and intensity as the interval between the operation and the follow-up observations lengthens. Much of the distress present during the first postoperative year tends to disappear subsequently. This improvement is brought about partly by the patient's realization that he must avoid large meals and that he can get along comfortably on six small meals a day. An equally important cause for improvement, however, is the capacity of the gastrointestinal tract to adjust itself to new conditions.

GASTROINTESTINAL MOTILITY

After subtotal gastrectomy, the normal motor functions of the stomach and upper intestines are deranged. Fluoroscopic observations reveal that in some cases material leaves the gastric stump with difficulty, but much more frequently the con-

medium enters the intestine with such rapidity the term "dumping stomach" has been used under these conditions. In an attempt to lessen subsequent motor disorders, many modifications of the method of gastric resection have been proposed, and a considerable argument has developed in the European literature concerning the relative advantages of the Billroth I and Billroth II operations. No conclusive evidence, however, has as yet been presented that one type of operation alters normal gastrointestinal motility less than does the other.²⁷ As will be indicated later, the gastrointestinal tract makes functional adjustments irrespective of the initial surgery, and other factors include the exact size and position of the stoma in determining the rate of gastric evacuation.

In the average patient who makes a good recovery from a subtotal gastrectomy, roentgenologic examination of the gastric remnant shows that this may be somewhat atonic in the early postoperative period, but subsequently it becomes small, appears to exhibit a high degree of tone and is often without a gas bubble.^{14, 16, 27} Ingested barium enters the small intestine rapidly, so that the gastric emptying time is usually much less than that of the normal stomach.^{15, 30} In time, however, the capacity of the gastric stump increases, a process that is effected by elongation of the greater curvature, the gas bubble reappears, and the stomach again assumes some of its reservoir functions. The partially resected stomach sometimes exhibits peristaltic waves,^{27, 31} but in other cases peristalsis is not seen,³² and the general motility pattern tends to be abnormal.¹⁵

Eventually, gastric emptying may occur intermittently and rhythmically, a phenomenon that has suggested to some that a new sphincter is formed by the gastric muscle that adjoins the stoma.^{14, 30} Schindler³³ states that the stoma, as seen through the gastroscope, usually appears patent and rigid, but that in 4 out of 41 patients who had undergone resection for ulcer a rhythmic, pyloruslike activity of the sphincter was seen. Most observers do not believe that a new sphincter forms at the site of the stoma, Vitkin²⁷ maintaining that the stomal aperture is opened and closed by the efferent jejunal loop.

Immediately distal to the anastomosis, the small bowel may dilate and form small accessory reservoirs in which the intestinal content pools before being transported farther down the intestine. Particularly if the gastric remnant is small or if total gastrectomy has been performed, jejunal reservoirs may become large and permanent.²³ Beyond these dilated areas, motility of the small intestine is said to be essentially normal,^{21, 23} or at least the contrast meal reaches the cecum and leaves the small bowel at a normal rate. In the growing monkey, however, puddling and dilatation occur in the lower small intestine after total gastrectomy.¹⁵

Unfortunately, the adjustments of the alimentary canal to subtotal gastrectomy do not proceed smoothly in all patients. Irregular or delayed emptying of the gastric stump may be marked, particularly in the early postoperative period. When emptying is delayed, the usual tendency is to focus all attention on the stoma in an effort to ascertain whether it is too narrow or is improperly placed, or whether there is some mechanical defect in its proximity.³⁴ The fact that many a so-called "nonfunctioning" stoma appears patent when the patient is reoperated on presented somewhat of a riddle until Ravdin and his associates^{35, 36} showed that hypoproteinemia may retard gastric evacuation, both through the pylorus or through a gastroenteric anastomosis. Since then the explanation of hypoproteinemia has been readily invoked to account for many postoperative disorders of gastrointestinal motility, although the evidence for hypoproteinemia may be quite meager. Hypoproteinemia undoubtedly can exert a marked influence on motility,^{37, 38} but other factors are at play, as indicated by the studies of Chauncey and Gray,³⁹ who could not correlate the level of the serum proteins and the rate of gastric emptying through a stoma.

The overemphasis that has been placed on the stoma in explaining abnormal gastrointestinal motility after gastrectomy can be ascribed to the concepts that have been held concerning the emptying mechanism of the normal stomach. In these concepts, the role of the pylorus has occupied a dominant position. Quigley,⁴⁰ however, has shown that in dogs the role of the pylorus is secondary and that gastric evacuation is chiefly controlled by the gastroduodenal pressure gradients. A few observations obtained by Abbott and his collaborators⁴¹ suggest that the same conditions obtain in man. It follows that poor gastric evacuation after subtotal gastrectomy in some cases has nothing to do with the stoma but is produced by a flattened or reversed gastroenteric pressure gradient.

The effect of certain foods on the motility of the upper gastrointestinal tract illustrates the role played by pressure gradients. When fats, hydrochloric acid or hypertonic solutions enter the intestinal loops distal to the anastomosis, the resected as well as the normal stomach exhibits delayed emptying.^{30, 42} This delay, it is now known, is produced by relaxation of the gastric musculature, not by sphincteric contraction. The consequent fall in intragastric pressure may be accompanied, in the case of gastrectomy, by a rise in intraenteric pressure, probably brought about by one of two mechanisms. Either the sudden influx of food activates the motor activity of the small intestine,^{32, 42} or the volume of the intestinal contents is rapidly increased by an outpouring of enteric juices, which take over the diluting functions normally carried out in the stomach.⁴³ The net result of these pres-

sure changes is a flattening of the gastroduodenal or gastrojejunal gradients, with delayed gastric evacuation. To prove that abnormal gradients account for some of the disorders usually ascribed to a defective stoma, better devices for recording intraenteric pressures are needed, but Ravdin, Royster, Riegel and Rhoads⁴⁴ find the indirect evidence strong enough to state: "The feeding mixture should not contain too much fat, for even though the mixture is placed in the jejunum gastric emptying will be delayed. Failure to recognize this fact has greatly increased the time of convalescence of many patients."

The incidence of functional disorders of gastrointestinal motility after gastrectomy is hard to compute. In the first few months after operation, such disorders are doubtless quite prevalent, and they, as well as mechanical stomal defects, should be considered as possible causes of improper gastric evacuation after partial gastrectomy. The edema of hypoproteinemia, if present, may partially occlude the stoma, but it also produces a serious derangement of all gastrointestinal motor functions.^{36, 38} With the aid of proper dietary management, functional disorders tend to subside during the first postoperative year, and subsequently they are encountered infrequently. Among 62 long-standing but poorly functioning gastroenterostomies — not gastrectomies — of various types, Eusterman, Kirklin and Morlock⁴⁵ found that only 6 could be ascribed to abnormal function.

The question naturally arises whether disorders of gastric emptying are particularly prevalent among those patients who experience postcibal distress after gastrectomy. Since the sudden inflation of a balloon in the duodenum often produces epigastric distress, nausea and giddiness,⁴⁶ some hold that these complaints occur after gastric resection because ingested food rapidly enters and distends the small bowel, particularly if the capacity of the gastric remnant is small or if total gastrectomy has been performed.^{47, 48} This theory is compatible with the facts that the postcibal symptoms tend to subside during the first postoperative year and that during the same time new reservoirs are being created, either by enlargement of the gastric stump or by chronic dilatation of the upper small bowel. On the other hand, if the gastric remnant empties very slowly because of some mechanical or functional disorder, it is possible that symptoms of epigastric distress and fullness after eating are produced by abnormal intragastric tension. It must be admitted, however, that the rate of gastric evacuation after subtotal resection, as judged by roentgenologic observations, and the incidence of postcibal symptoms shows, at the most, a weakly positive correlation.^{15, 16} Possibly functional disorders that are induced by the ingestion of certain foods are not evident after suspensions of barium sulfate are taken by mouth.

ABSORPTION

Previous reviews^{49, 50} on the effects of gastrectomy on absorption indicate that fat absorption is sometimes impaired, that fecal loss of nitrogen is excessive in a few scattered cases, but that the absorption of carbohydrates, so far as can be determined by available methods, is not decreased. Glucose administered intravenously is followed by a normal tolerance curve,²¹ but the oral test yields a curve that shows certain deviations from the normal.^{21, 32, 47, 51} In the gastrectomized patient, the blood-sugar level undergoes a steep rise, achieves a high peak and then drops rapidly to levels that may be definitely hypoglycemic. This curve probably depends on the facts that the resected stomach has little capacity to act as a reservoir and that the whole test dose enters the small intestine rapidly and is quickly absorbed. A strong stimulus is thereby exerted on the pancreas, which elaborates sufficient insulin to carry the blood-sugar to abnormally low levels after the absorption of glucose is completed. The secondary hypoglycemia may account for the weakness and perspiration experienced by some gastrectomized patients after taking a meal,³² but opinions on this point differ.⁴⁷

Intestinal digestion of protein apparently proceeds quite rapidly, even in the relative absence of gastric juice,⁵² and oral glycine-tolerance tests indicate that amino acids are readily absorbed by patients with gastric resections.⁵³ In harmony with these observations is the fact that an abnormal loss of fecal nitrogen is most unusual in patients with subtotal gastrectomies. After total gastrectomy, Emery's⁵⁰ dogs showed some fecal loss of nitrogen, but only 1 out of 4 carefully studied human subjects with total gastrectomy suffered from an increased nitrogen output in the stools.^{21, 23} Rekers, Pack and Rhoads²³ believe the nitrogen lost in this case to be of dietary origin, but there is considerable evidence that any process that increases the bulk of the stools may cause an increased fecal excretion of endogenous nitrogen.^{54, 55}

Of the various processes of absorption, that of fats appears to be the one most easily affected by gastrointestinal disorders of all types. Earlier reports of steatorrhea after gastrectomy are found chiefly in the European literature, but recent work on this problem has been carried out in this country by Rhoads and his associates.^{23, 56} These authors report that normal subjects on a diet of 80 gm. of fat a day lost 2 to 6 gm. of fatty material daily in the stools. In 3 patients with total gastrectomies, however, the fecal lipid loss was 11 to 23 gm. a day, although the daily fat intake was only 40 gm. The degree of steatorrhea was not relieved by giving bile salts, Lipocac or intrinsic factor (Ventriculin), nor did it appear to depend on a lack of gastric chyme, a lack of reservoir function or an increased intestinal transport. In 2 of the 3 patients, however, the giving of excess protein by mouth appeared to

improve fat absorption, and in 1 patient steatorrhea as reduced by the oral administration of pancreatic enzymes.

The improvement attending the exhibition of pancreatic material caused Rekers, Pack and Rhoads²³ to suggest that gastrectomy may somehow interfere with pancreatic function. The pancreas has previously been suspected of being responsible for post-gastrectomy steatorrhea, but conclusive evidence on this point has been difficult to obtain. After gastric resection, the duodenal contents is said to contain normal amounts of trypsin and diastase⁵⁷ and urinary diastase is not significantly changed.³² Atoxy-resistant lipase in the serum, believed to be specific for lipase of pancreatic origin,⁵⁸ is reported to be increased in one series of gastrectomies⁵⁹ and not changed in another.³² Santy and Mallet-Guy¹⁶ state that a rather constant production of pancreatic lipase is stimulated in the normal subject after intraduodenal instillation of hydrochloric acid, but that the response in gastrectomized patients is extremely variable and unpredictable, even if the same subject is repeatedly tested. They therefore conclude that gastrectomy disorganizes the mechanisms that control the flow of the external pancreatic secretions. In evaluating contradictory reports on the effects of gastrectomy on pancreatic function, it is well to remember that the determination of pancreatic enzymes is difficult and often unreliable.

After total gastrectomy for cancer, prothrombin levels may not return to normal, but this abnormality cannot be ascribed to faulty absorption of the fat-soluble vitamin K, for even injection of the vitamin may not affect the low prothrombin levels.²⁴ When growing monkeys are gastrectomized, the serum calcium and phosphorus may be diminished and bony changes suggestive of rickets may develop, even though vitamin D is given.¹⁷ In the past, Ivy²⁰ has ascribed disturbances in calcium metabolism in gastrectomized animals to a lack of gastric secretions and to changes in the acid-base equilibrium, but his recent work with growing monkeys suggests that absorption of the fatty vitamin D in these animals may be deficient.

ANEMIA

No doubt exists that the normal stomach, in the digestion of beef muscle, forms some substance that relieves pernicious anemia,⁶⁰ but, after total gastrectomy, this disease does not appear in laboratory animals and occurs extremely rarely in man.^{20, 61-63} Meulengracht⁶⁴ believed that he held the answer to this apparent contradiction when he demonstrated that in the pig the pylorus and the duodenum, not the fundus, contain the antianemic intrinsic factor. Subsequently, however, Meulengracht⁶⁵ was surprised to find that the stomach of patients dying of pernicious anemia showed extensive atrophy of the fundus and a normal ap-

pearance of the pyloric glands. The fallacy of Meulengracht's work lay, as Fox and Castle⁶⁶ showed, in applying his results in pigs to man; in the human stomach, the intrinsic factor is found principally in the fundus. The puzzle therefore still persists: Why do not patients with gastrectomies, particularly those with total gastrectomies, develop pernicious anemia?

As a matter of fact, a small number of patients do. In 1941, Meyer, Schwartz and Weissman⁶⁷ collected 54 cases of what they considered to be authentic cases of pernicious anemia following total gastrectomy. Since then another case has been reported,⁶⁸ but this case and others reported in the past have not had the benefit of a careful study such as Meyer and his associates devoted to their case. Before one can assert that true pernicious anemia occurs as a sequel to gastrectomy, control periods during which the patient receives extrinsic factor, reticulocyte counts before and during liver therapy, adequate follow-up periods and possibly even bone-marrow studies are necessary. Even if the evidence for pernicious anemia is unequivocal, the possibility still exists that some of the cases of pernicious anemia associated with gastrectomy are merely the result of coincidence.

Many patients and animals with gastrectomies do suffer from anemia, but this is usually of the normocytic and the normochromic^{23, 24} or hypochromic variety.^{21, 62, 69} The work of Dragstedt and his associates^{70, 71} indicates that the gastrectomized dog remains anemic on a stock diet but responds well when given excess iron by mouth. Many post-gastrectomy anemias also respond to ferrous sulfate,^{21, 62} but some remain refractory to both iron and liver.^{23, 62} Although parenteral liver extract is recommended for treating post-gastrectomy anemias,⁴⁸ iron is apparently more valuable, either given alone or in conjunction with liver extracts. In addition, proteins and vitamin B complex and its specific fractions, such as riboflavin,⁷² may also have to be given to excess if anemia after gastrectomy is to be prevented.

Petri and his associates^{15, 73} believe that gastrectomy in young swine is followed by a symptom complex closely similar to pellagra. In man, pellagra secondary to gastrectomy has been reported,^{74, 75} but in both cases the condition responded to adequate amounts of niacin (nicotinic acid) and vitamin B complex.

SUMMARY

The consequences of removing portions of the human stomach depend on the nature of the primary disease, the extent of the resection, the surgeon's skill and divers factors that vary with the patient's age, diet and mental attitude. By and large, however, the following statements can be made concerning patients who have undergone subtotal or total gastrectomy:

sure changes is a flattening of the gastroduodenal or gastrojejunal gradients, with delayed gastric evacuation. To prove that abnormal gradients account for some of the disorders usually ascribed to a defective stoma, better devices for recording intraenteric pressures are needed, but Ravdin, Royster, Riegel and Rhoads⁴⁴ find the indirect evidence strong enough to state: "The feeding mixture should not contain too much fat, for even though the mixture is placed in the jejunum gastric emptying will be delayed. Failure to recognize this fact has greatly increased the time of convalescence of many patients."

The incidence of functional disorders of gastrointestinal motility after gastrectomy is hard to compute. In the first few months after operation, such disorders are doubtless quite prevalent, and they, as well as mechanical stomal defects, should be considered as possible causes of improper gastric evacuation after partial gastrectomy. The edema of hypoproteinemia, if present, may partially occlude the stoma, but it also produces a serious derangement of all gastrointestinal motor functions.^{36, 38} With the aid of proper dietary management, functional disorders tend to subside during the first postoperative year, and subsequently they are encountered infrequently. Among 62 long-standing but poorly functioning gastroenterostomies—not gastrectomies—of various types, Eusterman, Kirklin and Morlock⁴⁵ found that only 6 could be ascribed to abnormal function.

The question naturally arises whether disorders of gastric emptying are particularly prevalent among those patients who experience postcibal distress after gastrectomy. Since the sudden inflation of a balloon in the duodenum often produces epigastric distress, nausea and giddiness,⁴⁶ some hold that these complaints occur after gastric resection because ingested food rapidly enters and distends the small bowel, particularly if the capacity of the gastric remnant is small or if total gastrectomy has been performed.^{47, 48} This theory is compatible with the facts that the postcibal symptoms tend to subside during the first postoperative year and that during the same time new reservoirs are being created, either by enlargement of the gastric stump or by chronic dilatation of the upper small bowel. On the other hand, if the gastric remnant empties very slowly because of some mechanical or functional disorder, it is possible that symptoms of epigastric distress and fullness after eating are produced by abnormal intragastric tension. It must be admitted, however, that the rate of gastric evacuation after subtotal resection, as judged by roentgenologic observations, and the incidence of postcibal symptoms shows, at the most, a weakly positive correlation.^{15, 16} Possibly functional disorders that are induced by the ingestion of certain foods are not evident after suspensions of barium sulfate are taken by mouth.

ABSORPTION

Previous reviews^{49, 50} on the effects of gastrectomy on absorption indicate that fat absorption is sometimes impaired, that fecal loss of nitrogen is excessive in a few scattered cases, but that the absorption of carbohydrates, so far as can be determined by available methods, is not decreased. Glucose administered intravenously is followed by a normal tolerance curve,²¹ but the oral test yields a curve that shows certain deviations from the normal.^{21, 32, 47, 51} In the gastrectomized patient, the blood-sugar level undergoes a steep rise, achieves a high peak and then drops rapidly to levels that may be definitely hypoglycemic. This curve probably depends on the facts that the resected stomach has little capacity to act as a reservoir and that the whole test dose enters the small intestine rapidly and is quickly absorbed. A strong stimulus thereby exerted on the pancreas, which elaborates sufficient insulin to carry the blood-sugar to a normally low level after the absorption of glucose is completed. The secondary hypoglycemia may account for the weakness and perspiration experienced by some gastrectomized patients after taking a meal,³² but opinions on this point differ.

Intestinal digestion of protein apparently proceeds quite rapidly, even in the relative absence of gastric juice,⁵² and oral glycine-tolerance tests indicate that amino acids are readily absorbed in patients with gastric resections.⁵³ In harmony with these observations is the fact that an abnormal loss of fecal nitrogen is most unusual in patients with subtotal gastrectomies. NEW HAMPSHIRE MEDICAL SOCIETY

PROCEEDINGS OF THE ONE HUNDRED AND FIFTY-THIRD ANNIVERSARY

House of Delegates, May 15 and 16, 1944

THE House of Delegates convened at the Hotel Carpenter, Manchester, on May 15, 1944, at 7:30 p.m., with Speaker George F. Dwinell presiding.

The following members answered the roll call:

The President, *ex-officio*
The Vice-President, *ex-officio*
The Secretary-Treasurer, *ex-officio*
P. R. Hoyt, Laconia (alternate for Benjamin W. Baker)
Richard W. Robinson, Laconia
W. J. Paul Dye, Wolfeboro
Francis J. C. Dube, Center Ossipee
A. C. Johnston, Keene
Richard C. Batt, Berlin
R. N. Jones, Whitefield (alternate for Leander P. Beaudoin, Berlin)
Arthur B. Sharples, Groveton
Arthur K. Burnham, Lebanon
Leslie K. Sycamore, Hanover
Howard N. Kingsford, Hanover
Donald M. Clark, Peterborough
Stillman G. Davis, Nashua
R. E. Biron, Manchester
Deering G. Smith, Nashua
Clinton R. Mullins, Concord
William P. Clough, Jr., New London
Gerard Gaudreault, Concord
Willard C. Montgomery, Epping
Harry B. Carpenter, Portsmouth

Fred Fernald, Nottingham
Roland J. Bennett, Dover
George G. McGregor, Durham
B. Read Lewin, Claremont
Donald G. Moriarty, Newport

The Speaker declared a quorum present, and appointed the Credentials Committee as follows: Drs. Dube (chairman), Carpenter and Lewin. Dr. Dube reported that the credentials were in order.

The Speaker appointed the Committee on Officers' Reports as follows: Drs. Mullins (chairman), Smith and Montgomery. He appointed the Committee on Communications and Memorials as follows: Drs. Kingsford (chairman), Sharples and Bennett. To the Committee on Nominations, he appointed Drs. Dye (chairman), Robinson, Burnham, Clark and Bennett.

On motion duly made and seconded, it was voted to omit the reading of the previous minutes, because of the publication of the proceedings.

On motion duly made and seconded, it was voted to dispense with the reading of the reports of the councilors, since they will be published in the proceedings.

About 30 per cent of the patients do not regain their normal weight, and some do not regain their preoperative weight.

About 10 per cent suffer from symptoms soon after taking a meal, particularly if the meal is large. These symptoms consist of epigastric distress and pressure, belching, nausea and weakness.

Some patients have soft stools, but very few suffer from persistent diarrhea.

The gastric remnant, which is at first small, gradually enlarges and resumes some of the reservoir function of the stomach. If the gastric remnant is extremely small, the small bowel dilates to form reservoirs near the anastomosis.

Even if the stoma is anatomically perfect, gastric evacuation after subtotal resection may be delayed by functional disorders.

The glucose-tolerance test shows a rapid rise in blood sugar, followed by a fall that may reach hypoglycemic levels. In a few cases symptoms occur during the hypoglycemic phase.

Carbohydrates and proteins are usually adequately absorbed, but some impairment in the absorption of fats may occur.

Pernicious anemia is an extremely rare sequela, but a normochromic or hypochromic anemia is not infrequent.

A nourishing diet, taken frequently in small quantities and fortified with vitamins and iron, often alleviates some of the complications of gastrectomy.

Symptoms and various motility disorders, which may be prominent during the first postoperative year, subsequently tend to correct themselves spontaneously.

Even when the undesirable sequelae of gastrectomy are marked, they rarely interfere with the patient's ability to work, and practically never are they so dangerous or distressing as the disease for which the gastric resection was undertaken. Hence the fact that these sequelae may occur cannot be considered in any sense as a contraindication to gastrectomy in adults. In the rare cases in which resection has to be considered in a growing boy or girl, it may be wise to limit the extent of the resection.

I asked each county society to have its members contribute \$1 apiece to the National Physicians' Committee. During 1943, \$191.00 was received from the several counties, as follows:

Carroll County	\$13.00
Cos County	36.00
Drafton County	75.00
Merrimack County	1.00
Rockingham County	38.00
Strafford County	28.00

In accordance with your directions the Committee on Medical Economics, with the assistance of the three officers of the Society and of Mr. Sulloway, formulated a plan for a medical-service corporation. Two special meetings of the House of Delegates were held to consider this plan in it developed, one in September and another in November. The Committee on Medical Economics will give you the intimate details in the report that they are making at this meeting.

Several members of the Society have discussed the Wagner Bill before county medical societies, Rotary Clubs and other organizations and have emphasized the fact that the Society has expressed its opposition to this plan for socialized medicine. The Wagner Bill will probably come to the fore in Washington within the next few months. It is still a very definite threat to the present system of the practice of medicine.

We must watch carefully House Bill 352, which was introduced into the New Hampshire Legislature at its recent special session and which was referred, without discussion, to the General Court, which assembles next January. This is a bill "relating to Sickness and Non-Industrial Accident Compensation." It is apparently a slightly modified Wagner Bill that is to be administered not by the federal government but by the State of New Hampshire.

In the several county societies during the past year there has been animated discussion of the Emergency Maternity and Infant Care Program for the families of servicemen, which was promulgated by the Children's Bureau in Washington. This matter was taken up at our meeting a year ago but no definite recommendation was made. A motion was carried that the "House of Delegates consider the Government plan for the payment of hospital and medical care of servicemen's wives at the time of delivery." It was pointed out that many of these patients were able to pay more than the \$35 fee that is provided by the Government, and a suggestion was made that the Government pay this money directly to the patient and that the doctor arrange a suitable fee in each case as he would with other private patients. It is doubtful, however, whether the Children's Bureau will accede to any such suggestion. In California the state medical society has rejected the plan of the Children's Bureau and has voted to treat these women as service cases.

Here in New Hampshire the present status of this program has been summarized as follows:

By and large our physicians are not enthusiastic about the program.

The following are the reasons for the reluctance; the first is the reason most frequently given:

The great fear that this program is an entering wedge for some type of government-controlled medicine.

The seemingly dictatorial way in which this program has been set up; the physician must accept the patient at the fee established by the program and cannot further charge the patient. There is no financial investigation, regardless of the financial status of the patient.

The over-all fee of \$35, which is regardless of the complications that may arise. This fee was set by the Maternity and Infancy Committee of the New Hampshire Medical Society. No state has a fee of more than \$50, and that is the maximum allowed by the Children's Bureau. Maine, New Hampshire and Vermont, comparable states, have a fee of \$35. Massachusetts has a fee of \$50. Physicians cannot understand why cases should not be treated individually. There is the fear that if such a program were here to stay, the physicians would be limited to \$35 and people would begin to think that that was all an obstetric case was worth.

However, most physicians doing obstetrics are participating in this program even though some of them may not be in accord with it, for several reasons:

Pressure from patients or public opinion.

This is an "all-or-none" program and takes care of both hospital and medical bills; if the physician does not sign the application blank, the patient cannot get hospitalization, so the physician, rather than penalize the patient, signs the blank and accepts the patient. This kind of regulation puts pressure on the physician to sign the application. Physicians object to this kind of pressure.

It should be noted that during the coming year the Children's Bureau is asking for seven prenatal examinations of the mother under the present fee schedule; that it is authorizing additional payment for "major non-obstetric surgical operations needed during pregnancy and six weeks postpartum for illness not attributable to pregnancy" at a rate not to exceed a total of \$50 for preoperative, operative and postoperative care; and that it is authorizing additional payment during pregnancy and six weeks postpartum for the home or hospital treatment of "intercurrent conditions not attributable to pregnancy which do not require major surgery." For this care the fee is not to exceed \$12 for the first week of illness and \$6 a week for subsequent weeks of illness. Similar authorizations with the same fees are made for an infant during its first year.

I have asked the Committee on Maternity and Infancy to consider this plan again at the present session and to advise whether or not members of this Society should continue the service under the present arrangement.

Because our program is crowded we have omitted the usual president's address and the report of the trustees. The report of the trustees will, however, be printed in the *New England Journal of Medicine* in a month or two and will be incorporated in the *Transactions* next year.

CARLETON R. METCALF, *Secretary-Treasurer*

On motion duly made and seconded, it was voted that the report of the Secretary-Treasurer be referred to the Committee on Officers' Reports.

Dr. Mullins, chairman of the Committee on Officers' Reports, then spoke as follows:

The Committee on Officers' Reports wishes to congratulate the Secretary-Treasurer on his successful attempt to curtail expenses. We recommend that the contribution to the Benevolence Fund be suspended for this year. The possibility of making this up later by a transfer from the General Fund is suggested. It is thought that the funds for the *New England Journal of Medicine* should be continued, since it serves a rather important purpose. The other suggestions as to Maternity and Infancy are dealt with in the respective committee reports.

Dr. Peters moved the adoption of this portion of the report, and this motion, duly seconded, was carried.

Report of the Committee on Maternity and Infancy

This is the tenth year of the study of maternal and infant deaths.

MATERNAL DEATHS

There were 24 maternal deaths in 1943. There were 9797 live births, thereby giving a maternal mortality of 2.45 per 1000 live births. This may be compared with the figure for 1942, when there were 15 maternal deaths and 9399 live births, a maternal mortality of 1.6 per 1000 live births.

These 24 maternal deaths have been classified according to the *International List of Causes of Deaths* as follows:

The secretary-treasurer, Dr. Carleton R. Metcalf, presented his report, as follows:

MEMBERSHIP, DECEMBER 31, 1943

PAID

Belknap County	23
Carroll County	13
Cheshire County	20
Coos County	25
Grafton County	53
Hillsborough County	104

Mechanics Bank (service charges)	1.60
Flowers (funeral of Mrs. Dennis E. Sullivan)	5.00
	<hr/> \$4109.00
	<hr/> 268.40
Balance, January 1, 1944	<hr/> \$4377.40

The Benevolence Fund on December 31, 1943, amounted to \$2572.78. Of this amount the principal was \$2081.8 and the accrued income \$490.83, part of which was from interest on United States bonds. During the past year we have received \$25 for this fund from the Women's Auxiliary of Merrimack County.

Our receipts have again been curtailed because members who are in the Service do not pay dues and because we have increased the allotment for the Benevolence Fund to \$1 from each member. We have had to draw on the General Fund to make up this deficit. We could decrease our expenses a little for the coming year, but there are on two items in our budget that would make an appreciable difference if they were eliminated. The first item is the *New England Journal of Medicine*. The *Journal* is sent to each member once a month and costs the Society between \$400 and \$500 annually. The second item is the Benevolence Fund. According to a vote of the House of Delegates this fund is to accumulate until it reaches \$10,000. The interest from the fund may then be used to help needy members of the Society. It will be several years, therefore, before this fund becomes effective, and even then the available interest each year will be relatively small. You may wish to discontinue the annual allotment toward this fund for the duration of the war.

We have already economized in our expenses by eliminating a donation of \$100, which for several years was given annually to the Women's Auxiliary, by limiting the annual meeting to one day and by choosing most of our guest speakers from nearby states rather than from distant ones.

Dr. Clarence O. Coburn, of Manchester, died on March 30, 1944. He was a former president of the Society and at the time of his death was a trustee, a councilor from Hillsborough County and a member of the Committee on Tuberculosis.

A year ago the House of Delegates made the following recommendations, which have been carried out:

Fifty dollars was given to the Cancer Committee for its work.

Your president and secretary have conferred with the State Welfare Department, with the result that the fee for old-age assistance cases have been increased. In accordance with the requirement of the federal government, however, the bills of the doctor must still be sent to the recipient and not to the Department.

Why should a physician be forced to sign the application blank, knowing that if he refuses to do so the patient will receive absolutely nothing? That is one outstanding question I have to the program. If the physician does not sign this slip of paper and give the patient the \$35 liberty, she gets nothing.

I see absolutely no reason for this clause's being inserted. A number of pitfalls that a man can find himself under this program is great. I have one case that could have been much worse. A young girl was in her first month of pregnancy, and in the second month she started miscarry. She lived nine miles from the office. I saw her in the middle of the night for two hours, and brought her to the hospital by ambulance. I kept her in the hospital for ten days and took her home myself. I made no house calls. She happened to be a girl who bled every time her period was due. I saw her in the office fifteen times. In the seventh month of pregnancy, she had a premature labor and delivered a 2½-pound infant boy, for some reason or other, made the grade; the mother developed cystitis. We discharged her on the fifteenth day. I had to make three calls to see her after she got home. We kept the baby in the hospital for eight weeks. This particular case could even have been worse, but it is a good example of what we are letting ourselves in for if we sign this blank.

There is also a tremendous difference between putting the program into effect in the cities and in the country towns. Those who practice in the cities can put these patients on ward service, but in the country we have to take care of them and call on them in their homes, no matter where they live.

The whole program has failed in its purpose, too. It would be interesting to note how many obstetricians in the cities are actually taking cases, and how many women are actually getting the care they want. I doubt if many of the obstetricians are taking them. They are going around, hunting for some doctor to take them for \$35, with the result that they get somebody who is not too good an obstetrician.

Dr. Gaudreault said that he was in perfect agreement with Dr. Clough. He thought that the forms could be submitted to the superintendents of hospitals and should be signed by them and that the doctors should be allowed to do what they please. He said that he would much rather deliver a case for nothing than be paid \$35 for his services. He believed that if anyone was willing to sign a paper he should receive at least \$50, as in Massachusetts and several other states. He recommended two different forms — one for the hospital and one for the physician.

Dr. Dube said that the superintendent of his local hospital was seriously disturbed by the whole affair. Apparently some time ago the hospital was offered a lump sum of \$50, but the option was then withdrawn and the hospital was asked to find the per capita cost for keeping a maternity patient. A detailed statistical report was wanted covering the number of patients in the hospital, the number of private rooms, the number of nurses on hand, the exact cost of food per meal and everything else. Apparently the hospital was being offered not over 15 per cent of the per capita cost of the care of the patient. Dr. Dube asked for information from the committee on the matter.

Dr. Smith then read the following extract from his report as delegate to the meeting of the American Medical Association:

The action of the federal government in making funds available for maternity and infant care for the wives and infants of enlisted men was approved and adoption was urged of a plan under which the federal government will provide for the wives of enlisted men a stated allotment for medical, hospital, maternity and infant care similar to the allotments already provided for the maintenance of dependents, leaving the actual arrangements with respect to fees to be fixed by mutual agreement with the wife and the physician of her choice. This action was similar to that taken by the New Hampshire House of Delegates last May. A copy of the resolution was sent to each congressman and each senator urging that a method of making available these funds be changed to an allotment basis. After considerable discussion in the House of Representatives, the proposal was rejected by a vote of 115 to 8.

He spoke as follows:

My feeling is that medical care is no different than the provision of fuel, food and shelter and clothing for the wives and children of the servicemen, and that medical care should be included in the allotments or allowances now given to servicemen. If the allowances, as they are called, are not large enough to take care of the wife and the children when they are sick or when the wife is going to have a baby, they should be increased. They are, as you know, a matter of record, varying according to the number of children a soldier has. If there are no children, the wife receives \$50 a month from the Government; if there is one child, she receives \$80 a month; if there are two children, she receives \$100, and there is an increase of \$20 for each additional child. Of this money, \$22 comes from the soldier's pay and the balance is made up by the Government.

Much as we want to take care of the soldier's wives, why should we do it at a cut rate when the Government is paying the full rate for other essential services?

Dr. Mary Atchison spoke as follows:

I am here neither to defend nor to sell. I feel, however, that the time has come for this controversial subject to be discussed frankly and openly. We in the State Health Department who have been delegated with the job of trying to administer this formidable program find ourselves in the middle, so to speak.

The fact is that funds are made available through the program by an act of Congress for the care of the specific group of individuals, namely, the wives and prospective mothers of servicemen, and up to this date there is no other source of funds for the women.

Medical care, to be sure, is absolutely no longer a luxury; it is a necessity, and it should be so classed as much as is food, clothing or shelter, as Dr. Smith has stated.

If the wife of a serviceman becomes ill with any other condition than pregnancy, no provision is made for her. Therefore, this program is, as designated, an emergency maternity program, and infant care is included in other states. We have been promised that the program is for the duration of the war and for six months thereafter, only. I think we should safeguard our rights in this regard.

I happened to be present at the state health officers' meeting in Washington when this matter was frankly discussed. The state health officers told the Children's Bureau officials exactly what they thought in regard to the manner of administration, the red tape, the requirements and the restrictions imposed in the administration of this program.

By and large, the physicians in New Hampshire have co-operated beautifully. They have given their time. They have, without liking it, given their services, and these have been of the best. We are grateful to you for doing that.

We sent out a bulletin to you before this meeting, and enclosed with it a short explanatory note. The bulletin had a formidable outline. We asked you to read and study it, so that you would know what the proposals or the policies are. We asked you in particular to note Item 4, which describes the services that are available under

	CLASSIFICATION	No. OF DEATHS
147 (<i>d</i>)	Puerperal embolism (during childbirth and puerperium)	5
146 (<i>c</i>)	Hemorrhage of childbirth and puerperium as placenta accreta, post partum	4
146 (<i>a</i>)	" " " " placenta previa with childbirth	2
148 (<i>a</i>)	" " " " " " " " " " h after delivery)	2
149 (<i>b</i>)	" " " " " " " " " " cesarean section	2
146 (<i>b</i>)	Hemorrhage — premature separation of placenta with childbirth	2
147 (<i>b</i>)	Infection during childbirth and puerperium	2
143 (<i>b</i>)	Hemorrhage — premature separation before delivery	1
144 (<i>d</i>)	Toxemia of pregnancy (death before delivery)	1
149 (<i>a</i>)	Accidents of pregnancy — inversion of uterus	1
140 (<i>b</i>)	Abortion with infection	1
148 (<i>b</i>)	Puerperal toxemia (albuminuria and nephritis).	1
Total	24

The committee has reclassified these for the purpose of this report in the following way:

CAUSE OF DEATH	No. of DEATHS
Accidents of pregnancy	6
Puerperal embolism	5
Inversion of uterus	1
Hemorrhage	9
Placenta previa	2
Premature separation	1
Retained placenta	3
Uterine inertia	3
Toxemia (all types)	4
Puerperal sepsis	4
Abortion with infection	1
Total	24

The 14 cases reviewed were listed on the death certificates as follows:

Embolism; endometritis (G6)
Hemorrhage and shock; premature separation of the placenta; death before delivery (G2)
Postoperative shock and hemorrhage; placenta accreta (G3)
Eclampsia; pregnancy with toxemia (G10)
Post-partum hemorrhage and shock; placenta previa complete (G4)
Embolism of lungs (acute schizophrenia) (G24)
Embolism; endometritis (G6)
Toxemia of pregnancy; acute nephritis (G11)
Hemorrhage; placenta previa (G13)
Coronary thrombosis following childbirth (G14)
Premature separation of placenta with shock and hemorrhage (G17)
Post-partum hemorrhage (G18)
Peritonitis and intestinal paralysis following cesarean section (G19)
Eclampsia (G21)

The 10 cases not reviewed were listed on the death certificates as follows:

Inertia of uterus with uterine hemorrhage
Toxemia of pregnancy
Purulent endocarditis; sevelar thrombi; atelectasis of lung; cesarean section
Pulmonary embolism; difficult delivery
Inversion of uterus
Pulmonary embolism; cesarean section
Shock; abruptio placentas; hydrocephalic breech
Cardiac collapse and generalized toxemia; penetration of uterus by piercing instrument; post-abortion uterus
Acute dilatation of stomach due to intestinal obstruction following operative delivery; acute peritonitis
Post-partum hemorrhage

Of the cases reviewed, in Cases G2, G3, G4, G6, G13 and G18 more information was needed in order to classify them. Cases G10, G17 and G21 were classified as due to the fault of the patient; Cases G11 and G24 were unavoidable; and Cases G14 and G19 were probably avoidable.

INFANT MORTALITY

Included in this group are those infants who died under one year of age. There were 420 infant deaths in 1943, giving an infant death rate of 42.9 per 1000 live births, compared with a rate of 33.5 in 1942. The causes of death were as follows:

CAUSE OF DEATH		No. of DEATHS
Deaths occurring during the first day:		
Prematurity		90
Birth injuries		22
Congenital deformities		15
Atelectasis		7
Congenital debility		2
Cerebral hemorrhage		1
Bronchopneumonia		1
Pulmonary emphysema		1
Syphilis		1
Unknown		1
Total		141

Deaths occurring during the first month exclusive of the first day:	
Prematurity	44
Congenital deformities	35
Birth injuries (all kinds)	5
Atelectasis	7
Diseases of gastrointestinal tract (diarrhea, enteritis and so forth)	11
Pneumonia (all types)	11
Hemorrhagic disease of newborn	1
Diseases of thymus gland	1
Congenital debility	1
Acute nephritis	1
Unknown	1
Total	121

Deaths occurring from the second to the twelfth month, inclusive:

Pneumonia (all types, with complications—empyema and so forth)	50
Congenital malformations	23
Gastroenteritis	2
Influenza	1
Whooping cough	1
Pyelonephritis	
Congenital debility	
Birth injury	
Suffocation	
Atelectasis	
Tuberculosis (pulmonary)	
Meningitis	
Cancer of intestines	
Endocarditis	
Otitis media	
Mental deficiency	
Convulsions	
Unknown	
Total	153

The causes of 211 still births were as follows:

CAUSE OF STILL BIRTH		No.
Causes	No.	Causes
Stillborn (cause unknown)	1	
Intrauterine death (cause unknown)	1	
Toxemia	1	
Difficult delivery	2	
Asphyxia neonatorum	2	
Prematurity	4	
Congenital malformations	2	
Premature separation of placenta		
Placenta previa		
Erythroblastosis		
Ruptured uterus		
Total	21	

The committee, with the aid of Dr. Burpee, the consultant, has formed the following recommendations in regard to Emergency Maternity and Infancy Care Program.

- That the physicians of New Hampshire, as a part of their war effort, participate in the maternity program in the future as they have done during the past year.

That the fee for services under this program be increased to \$50 per case.

That the program suggested for additional care of major surgical and medical conditions occurring in course of pregnancy not be accepted. (This recommendation is made because of the difficulty involved in determining the meaning of the term "qualified consultation as demanded under the program.")

That the child-health program be accepted under following conditions:

following conditions:

- The major surgical aid not to be included (a) because of the difficulty in determining the meaning of the term "qualified consultants").
- The aid not to be accepted for illnesses requiring

The medical aid to be accepted for illnesses requiring over two home or office visits. (This plan would eliminate many needless calls on essentially well babies and would avoid a great deal of extra work involved in applying for aid, authorizing the service and approving the records for payment.)

MARION FAIRFIELD, Chair
JOHN J. BOARDMAN
BENJAMIN P. BURPEE, Consul

Dr. Clough then spoke as follows:

I think there is not one of us who is not perfectly willing to do anything we can for servicemen's wives, we are unwilling to have this thing forced down our throats.

By the way there is nothing compulsory about this. The program is accepted by the medical society in principle. If you do not want to participate in it, you can say at you are too busy, that you would like to do it but not. That is your problem.

Dr. Gaudreault remarked that the program still the doctor "holding the bag."

Dr. Atchison replied that under the maximum \$35 the doctor "was holding the bag," and that was a little fairer. She thought that if every-asked himself, "How much do you actually ect?" he would admit that it would be somewhere he vicinity of \$50.

The Committee on Officers' Reports moved that

this program as recommended by the Committee on Maternity and Infancy be accepted. He outlined these recommendations as follows:

That the physicians of New Hampshire, as a part of their war effort, participate in the maternity program in the future as they have done during the past year.

That the fee for services under this program be increased to \$50 per case.

That the program suggested for additional care for major surgical and medical conditions occurring in the course of pregnancy be not accepted.

This motion was duly seconded and was carried with three dissenting votes.

CASE 30351

PRESENTATION OF CASE

First admission. A fifty-nine-year-old housewife entered the hospital because of "heart trouble." The patient had been in apparent good health until about three or four months before entry, when she developed chills, fever, chest pain and cough, diagnosed and treated as pneumonia by her physician. She recovered in about one month, but remained in bed except for about two or three hours daily. About two months before admission she had sudden attack of agonizing, squeezing pain in the chest associated with inability "to catch her breath." She said that she felt as though she were "dying." The pain and dyspnea lasted for five hours and were finally relieved by a hypodermic injection by her physician. From that time on, she had attacks of nocturnal dyspnea occurring two or three times a week, which were relieved by injections, the nature of which is not recorded. She had marked orthopnea, requiring three pillows. One month before entry she developed frequent attacks of nausea and vomiting.

At forty-one years of age, following an episode of polydipsia, polyuria and weakness, she was found to have diabetes. The diet was regulated and she was placed on 4 units of insulin three times a day. Four months before admission the insulin was re-

*On leave of absence.

duced to 4 units twice a day. Since no sugar appeared in the urine, the insulin was not increased during the course of the pneumonia, and one and a half months before entry it was stopped completely without any symptoms. One year before admission she experienced swelling of the ankles, and about six months later was found to have a systolic blood pressure of about 200. The past history was otherwise negative.

Physical examination showed a well-developed but poorly nourished dyspneic woman. The heart was enlarged. The apical impulse was palpable in the anterior axillary line. The sounds were strong, labored and regular. The first sound was clear. No definite murmurs were heard. The aortic second sound was greater than the pulmonic. The liver edge was palpated two fingerbreadths below the costal margin. There was moderate sacral and ankle edema. Ophthalmoscopic examination showed irregular thickening of the arterioles and the silver-wire reflex, as well as a number of small flame-shaped hemorrhages at the branching of the vessels. Foci of old hemorrhage and spots of exudation were present.

The blood pressure was 254 systolic, 100 diastolic. The temperature was 100°F., the pulse 90, and the respirations 20.

Examination of the blood showed a red-cell count of 2,000,000, with 6 gm. of hemoglobin. The white-cell count was 6600, with 60 per cent neutrophils. A blood Hinton test was negative. The urine was slightly cloudy, with a specific gravity of 1.012 and a pH of 7.5; it gave a + + + + + test for albumin but no reaction for sugar, diacetic acid, acetone or bile. One or 2 red cells and 3 or 4 white cells per high-power field were seen in the sediment. A culture yielded *Staphylococcus albus* and colon bacilli. Stool examination was negative.

An x-ray film of the chest showed an enlarged heart whose borders, however, were obscured by fluid in the pleural cavities. The pulmonary markings were prominent. The nonprotein nitrogen was 77 mg. per 100 cc., the protein 4.8 gm., and the

the program. Your Committee on Maternity and Infancy has studied this program with a great deal of care and albeit, after much frank discussion, they do not approve of all of it. It is within our rights to prepare a program, provided you will accept it in principle advising us as to the parts of the program that you think might be workable. We are asking for a ceiling fee for maternity care of \$50, and if this is accepted by you I am almost certain we shall get it. The reason we have not asked for \$50 before is that when the program was first started, the ceiling set by the Bureau was \$35. Gradually, the various states studying the matter reached the conclusion that a maternity case could not be handled for \$35. It was stated that if that was all such a case was worth, the physicians were not going on record as saying that they would lower their standards in order to give a \$35 delivery. So Massachusetts and some of the larger states asked for \$50 and got it. I understand from my colleagues in Vermont and Maine that they are going to do the same.

In the beginning, in such a case as Dr. Clough described, we were not allowed to make any additional provisions. As stated in the bulletin we shall be allowed to pay an additional amount for time and travel on a mileage basis. We do not like these limitations any more than you do. These policies were worked out by the Children's Bureau with its medical advisory committee, which is made up of some of the best minds in the country — representatives of the American Medical Association, obstetricians, pediatricians and men recognized in the field of medicine as the best.

This is a mass-production type of program. It was designed, of course, to fit the United States as a whole. We cannot possibly say that one plan is going to fit the whole situation. From letters that we have received we have assurances that we can use our own judgment.

I want to compliment Dr. Chamberlain for the conscientious manner in which she has tried to administer the program. I am not saying whether or not it should be adopted, but I want you to know that we are constantly aware of the needs of the profession and its problems, and our only purpose is to try to protect its interests so far as a program of this type is concerned.

When this act was passed by Congress there must have been some reason for it, and this was pressure from certain groups. The American Red Cross, all the labor unions and others simply went to Washington and demanded that something be done.

As I understand it, the entire intent of the program is a service to the serviceman and his family.

The matter of the payment of funds to the family was also discussed. It was thought that the most democratic thing to do was to give the patient a sum of money and say to him or her, "Pay your bill." However, we in the Department of Public Welfare, who administer the public-relief moneys, know that the grocer gets paid, the furniture dealer gets paid, the dry-goods store gets paid, but the doctor does not get paid. When the patient gets the money, there is nothing that says, "You must pay the doctor." Human beings are human beings; therefore, from an administrative standpoint, it is much better, in providing services, in order to safeguard everything, that the doctor be paid by an official agency. The official agency is the department that has in it medical personnel. The only reason that the payment is made in this way is that the doctor can thus be sure of what he is getting.

Dr. Mullins asked whether if this program were rejected it would work a real hardship on the women concerned in this state.

Dr. Atchison replied that, although she had no statistics to bear out her statement, the program was needed. The Grenier Field Army Base, for instance, had previously taken care of the Army wives, but had now discontinued this service which meant that the women with the \$50 allotment were put on their own and would have to obtain care. She did not see why the doctor should

"take the rap," since the patients had to pay the hospitals.

Dr. Mullins asked whether the hospitalization part of the infant-care program was connected with the physician's care, and whether the hospital care would still be allowed.

Dr. Atchison believed that the principle was the same, and Dr. Chamberlain said that it was the same setup. Dr. Atchison explained that the intention was that the patient should be assured of medical care of some sort, and of course would get hospital care, too. The hospital would be paid on a per diem ward cost basis, which would vary with different hospitals. This cost was to include diagnostic procedures, x-ray examinations, laboratory fees and what not.

Dr. Dube pointed out that this cost was nearly \$6 a day. Dr. Atchison agreed, and remarked that if a maternity case was complicated, the physician would take a loss, but that if he had 100 cases and the majority of them were normal, he would not fare too badly. She added that, as a matter of fact, many physicians in the rural areas seemed to favor this program more than one would suspect. The city physicians, of course, had a higher overhead and they claimed that \$35 was nothing but that \$50 was a little better. However, in some states the physician got at the most \$15 for a delivery, and even then could not collect it, so that many of them were willing to handle the case on the present basis.

Dr. Clough said that it depended on what type of obstetrics one was practicing. He believed that the price for all should be elevated, not brought down. It seemed to be the accepted attitude that obstetrics was not worth much, but this idea was absolutely wrong.

Dr. Atchison agreed. She added that of course it could not be said that one physician was worth \$100 and another \$25 and still others \$15 or \$50, so that a uniform method was the only possible one for proper administration of payments.

Dr. Dye asked whether women who accept war rate care could have private rooms. Dr. Atchison replied, "No."

Dr. Gaudreault said that he still believed that the doctor and the superintendent of the hospital should both sign the form, and have the doctor free to give the patient the care she needed and still not deny her the privilege of having her hospital care paid for by the Government.

Dr. Atchison spoke as follows:

Under certain conditions under which these services are made available, Dr. Chamberlain and I see a loophole. For instance, these services may be authorized provided similar services are not available. Suppose there is not a service in the hospital and that there is a clinic available in a certain town to which the patient can go. If she so chooses, all right. A wife has three choices under the program, including all types of available facilities. She may not want to go to a clinic, and may prefer a private practitioner and ask for one.

anatomopathological conference that Dr. Richard C. Cabot conducted years ago, when he was handed an abstract of the history on the spot.

It seems reasonable that a diagnosis of pneumonia was made following the episode of chills and fever, chest pain and cough. The next attack of chest pain and dyspnea lasted for five hours. Was it substernal?

DR. BENJAMIN CASTLEMAN: It does not say.

DR. CHAPMAN: The pain was squeezing and constricting, so I suspect that it was substernal.

Hypertension was discovered a year before entry, and the patient had edema of the ankles at that time. On physical examination advanced arteriosclerotic changes were found in the eyegrounds.

According to the laboratory notes the red-cell count was surprisingly low, and it is interesting that the specific gravity of the urine was so low (1.012). When a patient is dehydrated at entry one always looks at the first gravity, because it is of more significance than subsequent tests in the hospital, since the patient is usually given extra fluid. I assume this was an admission specimen.

DR. CASTLEMAN: The specific gravity of the urine is at first 1.012, then 1.010, 1.008 and 1.020.

DR. CHAPMAN: The record states that after eighteen days the patient's condition improved. I am not so impressed with the improvement.

The electrocardiographic changes are more than consistent with left ventricular enlargement; they suggest damage to the anterior wall of the myocardium.

The patient had a potential diabetic background. Her blood sugar was slightly above normal, but not very high. She evidently was diabetic and also hypertensive. I do not see much point in giving 4 units of insulin three times a day, since this is an unnecessary burden to place on a patient. She might have taken one dose or regulated her diet.

A year before admission she developed hypertension and then began to have swelling of the ankles.

She entered the hospital with the story of being well until the sudden onset of chills and fever, the diagnosis of pneumonia at the left base having been made. Pulmonary infarction is often treated as pneumonia because the signs and clinical story are often similar. Since this patient continued to have symptoms, in retrospect one has to consider infarction strongly. The second attack may have been due to more pulmonary emboli. She had changes in the circulation. Linton and his co-workers¹ in a recent publication covering 202 cases of pulmonary embolism and infarction state that 70 per cent occur in the left lower lobe, although most reports, including that of Hampton and Castleman,² name the right lower lobe as the favorite site. I think that is significant. I believe that this patient had an embolus and not true pneumonia.

The next question is, Was this true angina or did she have coronary occlusion with myocardial infarction of the anterior wall? The fact that it lasted five hours suggests that she had infarction. That is too long for angina.

Then she re-entered the hospital and died in uremia. I think that the persistent pneumonia, the persistent hypertension, the persistent edema and the whole clinical story — the gradual going down hill and death in uremia after a long hospital entry — favor the thing that we have been led to suspect, that is, an intercapillary glomerulosclerosis, which has been described by Kimmelstiel and Wilson³ and which happens so often in diabetics. I believe that Dr. Castleman will show us kidneys with deposits between the capillary tufts. Edema is an outstanding clinical feature in these patients. Certainly this woman had edema, and they even used Southey tubes for it. She had pericarditis with a pericardial friction rub. As a routine interpretation we might say that the electrocardiogram showed infarction of the anterior wall with inversion of the T waves and a deep Q₃, with inversion of CF₄ and CF₅. I believe, however, that she did not have an occlusion, because the pericarditis could have produced these changes. In other words coronary occlusion with infarction in the anterior wall can be simulated in all respects by pericarditis, with or without effusion. An excellent paper on that point has just been published by Wolff,⁴ who reported 5 cases seen at the Beth Israel Hospital.

The development of the blowing diastolic murmur does not disturb me. I do not believe that we have to think of aortic regurgitation, because the murmur disappeared when the patient became compensated. I wish that Dr. Butler would comment on the blood chemical findings.

DR. ALLAN M. BUTLER: One gram of ammonium chloride daily had marked effect in producing an acidosis, the carbon dioxide dropping to 13 millimols and the chloride rising to 114 milliequiv. I think that makes sense in a patient who has marked renal damage and hence does not produce ammonia and cannot excrete sodium and chloride differentially. The next time they gave 1 gm. of ammonium chloride four times a day, but only for one day.

I suppose that this patient had marked arteriosclerosis and vascular nephritis. I wonder about the diabetes. She probably had it, but we are given no real evidence except that someone said so.

DR. CHAPMAN: She was given insulin; in other words, someone thought she had it. We do not know how limited the diet was in carbohydrate.

DR. BUTLER: There is no evidence of diabetes in the story given us, and we have to assume that it was present. On the other hand, she was not paying much attention to diet, not taking insulin and not showing much evidence of diabetes.

DR. CHAPMAN: I am interested that she put out 5 per cent of phenolsulfonephthalein dye at the end of

blood sugar 123 mg. The carbon dioxide was 20.6 millimols per liter, and the chloride 103.2 milliequiv. The fluid intake was limited to 1800 cc. She was given 0.011 gm. ($\frac{1}{6}$ gr.) of morphine and 0.2 gm. (3 gr.) of digitalis three times a day for two days and 0.1 gm. ($\frac{1}{2}$ gr.) of the latter daily thereafter, as well as 1 gm. (15 gr.) of ammonium chloride daily. After the second hospital day she was started on protamine zinc insulin, 20 units daily for two or three days.

During the first hospital week she vomited considerably and complained of subxiphoid pain. The vomiting finally stopped. On the seventh hospital day the nonprotein nitrogen was 90 mg. per 100 cc. The protein was 6.0 gm. per 100 cc., with an albumin-globulin ratio of 2. The carbon dioxide was 13.2 millimols per liter, and the blood chloride 113.8 milliequiv. She was given 0.13 gm. (2 gr.) of sodium phenobarbital subcutaneously three times a day. A phenolsulfonephthalein test gave less than 5 per cent excretion at the end of an hour. In the course of the next eighteen days her condition improved remarkably; the carbon dioxide rose to 16.4 millimols per liter, and she was discharged on 0.1 gm. ($\frac{1}{2}$ gr.) digitalis daily and limited fluid intake.

Final admission (one and a half months later). Following discharge the patient failed to follow directions. She was irregular in taking digitalis, drank "lots" of water and did not keep her appointment at the Out Patient Department. She became progressively more dyspneic, with increasing edema and marked orthopnea. Eight hours before admission she developed severe respiratory distress.

Physical examination showed a slightly cyanotic woman in acute dyspnea. The lung bases were dull up to the fifth interspace. Many coarse rales and wheezes were heard throughout. The breath sounds were decreased at the bases. The heart was enlarged to 4 cm. beyond the midclavicular line. A low-pitched early mid-diastolic blowing murmur was heard at the aortic region. A pericardial friction rub was audible at the base. The abdomen was negative. There was marked pitting edema of the ankles, extending to the level of the lower thorax, where only a slight pitting edema was present.

The blood pressure was 210 systolic, 110 diastolic. The temperature was 97.6°F., the pulse 120, and the respirations 30.

Examination of the blood showed a red-cell count of 3,200,000, with 5.5 gm. of hemoglobin. The white-cell count was 6400, with 60 per cent neutrophils. The urine was cloudy, with a specific gravity of 1.008 and a pH of 7.5; it gave a +++ test for albumin and contained a trace of acetone. The sediment had 1 or 2 white cells per high-power field. The nonprotein nitrogen was 140 mg. per 100 cc., and the carbon dioxide 22.3 millimols per liter; the protein was 6.0 gm. per 100 cc., with an albumin-globulin ratio of 1.2. An electrocardiogram showed a

rate of 95. The PR interval was 0.12 second. Slight left-axis deviation was present. ST₁ and ST₂ were slightly depressed, with low inversion of T₁, T₂ and T₃. Q₃ was deep, and the T wave was low in CF₄ and low and inverted in CF₅.

She was given 0.011 gm. of morphine sulfate and two transfusions of 250 cc. of whole blood each. She was also given 0.2 gm. of digitalis for two days, followed by 0.1 gm. daily, 1 gm. of ammonium chloride four times a day (for four doses), followed by 2.2 cc. of Mercupurin intravenously, and daily infusions of 25 per cent dextrose in water.

On the fourth hospital day she vomited several times. The urine continued to remain alkaline and to give a +++ or ++++ test for albumin. The basal rales diminished. The friction rub was still present, but the aortic diastolic murmur could not be heard. The blood pressure was 210 systolic, 100 diastolic. The nonprotein nitrogen was 120 mg. per 100 cc. The carbon dioxide was 20.2 millimols per liter, the chloride 93.3 milliequiv., and the blood sugar 15 mg. per 100 cc. An x-ray film of the chest showed fluid in both pleural cavities. The urinary output was 500 cc. on an intake of 1250 cc.

On the ninth hospital day pitting edema was noted extending to the neck. The pericardial friction rub was heard in the third interspace to the left of the sternum. On the eleventh hospital day 1200 cc. of clear, yellow fluid was withdrawn from the right thorax. The specific gravity of the fluid was 1.005 and it contained 180 cells per cubic millimeter, with 10 per cent red cells, 45 per cent lymphocytes, and 45 per cent monocytes. On the thirteenth hospital day she had severe, acute respiratory distress and considerable discomfort because of severe edema in the legs. Another chest tap, on the fourteenth hospital day, gave 1300 cc. of fluid from the right side and 1100 cc. from the left. The dyspnea improved temporarily but during the following week it increased. On the twenty-third hospital day Southey tubes were inserted in both ankle and thoracentesis yielded 1000 cc. from the right and 800 cc. from the left, with much improvement in the dyspnea. In the next three weeks, however repeated chest taps were necessary. On the forty-ninth hospital day she became nauseated and began to vomit. She had considerable headache. The nausea and vomiting persisted despite atropine. The pericardial friction rub became louder; the nonprotein nitrogen was 108 mg. per 100 cc. The vital capacity was 1300 cc. She continued to get digitalis.

Her condition became progressively worse, and she died on the sixty-third hospital day.

DIFFERENTIAL DIAGNOSIS

DR. EARLE M. CHAPMAN: Through an error I received the wrong clinical abstract but I shall attempt to discuss this case without having prepared it. In other words, it resolves into the type of

pericarditis, which at the time of autopsy was in the healing stage. There has been a lot of discussion about the appearance of the myocardium in patients with renal failure. Most people believe that there is no definite myocarditis due to renal failure, though Gouley⁶ has stated that there is a characteristic myocardial degeneration.

DR. CHAPMAN: How extensive was the recent infarction?

DR. CASTLEMAN: It was very extensive and certainly not more than a week or two old.

DR. CHAPMAN: Then it could not explain the changes in the electrocardiogram taken sixty days before.

DR. CASTLEMAN: No.

DR. CHAPMAN: They might well have been explained on the basis of the acute pericarditis that he had had at the time.

DR. CASTLEMAN: Yes.

The kidneys weighed 250 gm. and showed numerous scars throughout. Microscopically we found the condition that Dr. Chapman predicted. Most of the glomeruli showed extensive hyalinization in such a fashion as to give the tufts a lobulated appearance, the sclerosis being predominantly intercapillary. Many of the peripheral capillaries were patent. This is the characteristic picture described by Kimmelstiel and Wilson.³

DR. BUTLER: How about the small arterioles?

DR. CASTLEMAN: There was a goodly amount of vascular nephritis as well.

The only remnant of the old process in the left lower lung was a fibrous diaphragmatic pleuritis. Unfortunately, sections through the underlying parenchyma were not taken for microscopic examination, so that we do not know whether the lesion was due to an infarct or pneumonia.

CASE 30352

PRESENTATION OF CASE

A twelve-year-old schoolboy entered the hospital complaining of pain in the right hip.

The patient had been well until three months before admission, when he slipped and fell on his right hip. He developed pain and limitation of

motion which became progressively worse two to three weeks before admission.

Physical examination showed a well-developed, well-nourished boy in no acute distress. The heart, lungs and abdomen were negative. There was tenderness over the lateral aspect of the right hip, and marked limitation of motion due to spasm and pain.

The blood pressure was 125 systolic, 80 diastolic. The temperature was 100°F., the pulse 85, and the respirations 25.

Examination of the blood showed a white-cell count of 8600, with 71 per cent neutrophils, 22 per cent lymphocytes, 4 per cent monocytes, 2 per cent basophils and 1 per cent eosinophils. The hemoglobin was 12.8 gm. per 100 cc. The urine was normal. A blood Hinton test was negative.

Anteroposterior stereoscopic films of the pelvis showed destruction of the right ilium along the entire region of the right sacroiliac joint (Fig. 1). The process appeared to extend well into the ilium and to involve the medial half of the iliac crest. The joint itself and the sacral side of the joint did not appear to be involved. There was a soft-tissue mass overlying the right ilium that measured 9 cm. in diameter. X-ray films of the spine showed moderate scoliosis toward the right, which might have been due to splinting and muscle spasm. The kidney shadows were of average size and shape and in the usual position. There were no other areas of destruction in the pelvis, spine or the thoracic cage. Roentgenogram of the chest was negative.

Following admission, the patient seemed to be fairly comfortable so long as he was confined to bed. He continued to run a low-grade fever. Other white-cell counts were 13,900 and 19,200.

On the second hospital day an operation was performed.

DIFFERENTIAL DIAGNOSIS

DR. CHANNING C. SIMMONS: There are some data that are not given in the protocol that might be of value in making a diagnosis. The blood chemical findings, for instance, would be of value in ruling out certain bone tumors, and a tuberculin test would help in ruling out tuberculosis of the sacroiliac joint. No mention is made of lymph-node involvement.

DR. BENJAMIN CASTLEMAN: The serum calcium was 9.4 mg. per 100 cc., the phosphorus 4.3 mg., and the phosphatase 1.7 Bodansky units. A tuberculin test was not done.

DR. SIMMONS: In other words the phosphatase was on the low side of normal. The serum protein would be of value in ruling out plasma-cell myeloma, which I doubt that this boy had.

Are the x-ray films available?

DR. LAURENCE L. ROBBINS: These films show a destructive process involving the ilium, with apparent extension up to but not involving the

one hour. Before we⁵ studied the fractional excretion of dye in nephritic patients, it was difficult to estimate prognosis on the basis of any single test. Our work showed that there were no survivals after one year if the dye excretion fell to 5 per cent or less in fifteen minutes, and it has proved on many occasions to have prognostic value. This case substantiates that.

DR. BUTLER: How about the weight? When they gave ammonium chloride, the serum protein increased. One wonders if that was an error on the part of the laboratory or whether the serum protein went up because of loss of edema and of weight.

DR. CHAPMAN: No weight is given on the first admission.

DR. BUTLER: If one is treating patients with cardiac failure and renal disease, an excellent way to tell what is going on is to weigh them now and then.

DR. CHAPMAN: My diagnoses are diabetes, arteriosclerosis, hypertension and intercapillary glomerulosclerosis — the type described by Kimmelstiel and Wilson. I believe that she died in kidney failure from that type of kidney disease and that she had an old pulmonary infarction at the left base. I do not believe that she had recent coronary occlusion with infarction of the anterior myocardial wall, but that these electrocardiographic changes were produced by pericarditis and effusion; possibly there was an old coronary occlusion that dated back to the first episode, two months before admission.

DR. WILLIAM BECKMAN: The patient had lost 20 pounds. On entry she weighed 139 pounds, and two weeks later 119.

DR. BUTLER: We can assume then that the ammonium chloride had a diuretic and a dehydrating effect, with the increase in serum protein that Dr. Chapman noted.

DR. BECKMAN: During the first admission she definitely improved clinically so far as decompensation was concerned. When I went over her the first time I thought of intercapillary glomerulosclerosis, but finally ruled it out because she did not have the retinopathy typical of diabetes. The retinal changes were characteristic of arteriosclerosis. So I decided that she had arteriosclerotic kidneys and hypertension.

DR. BUTLER: Can you tell us whether she really did have diabetes?

DR. BECKMAN: We were not certain, since we merely did the routine tests. She continued to excrete a little sugar each day. She never had a blood sugar higher than 155 mg. per 100 cc., and she was given insulin on the theory that all diabetic patients should receive insulin for three days.

DR. CHAPMAN: Was a glucose-tolerance test done? I am impressed by the number of patients in the Out Patient Department on whom a diagnosis of diabetes is made on a single test showing sugar in

the urine. It seems that glucose-tolerance tests are not done often enough to establish a definite diagnosis.

DR. BUTLER: In many of the patients you are speaking about there is no doubt about the diabetes. A typical history, a high blood sugar and sugar in the urine usually establish the diagnosis of diabetes. Thus there is no need of doing a glucose-tolerance test. In the doubtful case it is reasonable to ask for such a test.

DR. CHAPMAN: I agree.

CLINICAL DIAGNOSES

Chronic vascular nephritis, with uremia.
Hypertensive heart disease.
Congestive failure.

DR. CHAPMAN'S DIAGNOSES

Diabetes.
Arteriosclerosis.
Hypertension.
Intercapillary glomerulosclerosis.
Uremia.
Pericardial effusion.
Pulmonary infarction, left base?
Coronary occlusion (two months old)?

ANATOMICAL DIAGNOSES

Intercapillary glomerulosclerosis, marked.
(Uremia.)
Diabetes mellitus.
Myocardial infarction, recent and old.
Coronary sclerosis with old occlusion.
Cardiac hypertrophy, hypertensive type.
Hydrothorax, bilateral.
Bronchopneumonia, terminal.
Pericarditis, healing.

PATHOLOGICAL DISCUSSION

DR. CASTLEMAN: The autopsy on this patient showed a hypertrophied heart weighing 450 gm. The coronary arteries were markedly sclerotic, and in the descending branch of the left we found an old occlusion, with a corresponding healed infarct in the myocardium. In addition there were scattered through the left ventricular wall yellow and pinkish-red areas that looked like the lesions of acute infarction. Microscopic examination showed acute myocardial infarction, although we were unable to find a recent thrombosis. This infarction showed polymorphonuclear infiltration and necrosis of muscle fibers, so that I do not believe that there is any question about the diagnosis. Also, the involved areas were in the endocardial side of the myocardium rather than in the pericardial side, so that they were not due to an extension from the

icarditis, which at the time of autopsy was in the healing stage. There has been a lot of discussion about the appearance of the myocardium in patients with renal failure. Most people believe that there is no definite myocarditis due to renal failure. Though Gouley⁶ has stated that there is a characteristic myocardial degeneration.

DR. CHAPMAN: How extensive was the recent infarction?

DR. CASTLEMAN: It was very extensive and certainly not more than a week or two old.

DR. CHAPMAN: Then it could not explain the changes in the electrocardiogram taken sixty days before.

DR. CASTLEMAN: No.

DR. CHAPMAN: They might well have been explained on the basis of the acute pericarditis that he had had at the time:

DR. CASTLEMAN: Yes.

The kidneys weighed 250 gm. and showed numerous scars throughout. Microscopically we found the condition that Dr. Chapman predicted. Most of the glomeruli showed extensive hyalinization in such a fashion as to give the tufts a lobulated appearance, the sclerosis being predominantly intercapillary. Many of the peripheral capillaries were patent. This is the characteristic picture described by Himmelstiel and Wilson.³

DR. BUTLER: How about the small arterioles?

DR. CASTLEMAN: There was a goodly amount of vascular nephritis as well.

The only remnant of the old process in the left lower lung was a fibrous diaphragmatic pleuritis. Unfortunately, sections through the underlying parenchyma were not taken for microscopic examination, so that we do not know whether the lesion was due to an infarct or pneumonia.

motion which became progressively worse two to three weeks before admission.

Physical examination showed a well-developed, well-nourished boy in no acute distress. The heart, lungs and abdomen were negative. There was tenderness over the lateral aspect of the right hip, and marked limitation of motion due to spasm and pain.

The blood pressure was 125 systolic, 80 diastolic. The temperature was 100°F., the pulse 85, and the respirations 25.

Examination of the blood showed a white-cell count of 8600, with 71 per cent neutrophils, 22 per cent lymphocytes, 4 per cent monocytes, 2 per cent basophils and 1 per cent eosinophils. The hemoglobin was 12.8 gm. per 100 cc. The urine was normal. A blood Hinton test was negative.

Anteroposterior stereoscopic films of the pelvis showed destruction of the right ilium along the entire region of the right sacroiliac joint (Fig. 1). The process appeared to extend well into the ilium and to involve the medial half of the iliac crest. The joint itself and the sacral side of the joint did not appear to be involved. There was a soft-tissue mass overlying the right ilium that measured 9 cm. in diameter. X-ray films of the spine showed moderate scoliosis toward the right, which might have been due to splinting and muscle spasm. The kidney shadows were of average size and shape and in the usual position. There were no other areas of destruction in the pelvis, spine or the thoracic cage. Roentgenogram of the chest was negative.

Following admission, the patient seemed to be fairly comfortable so long as he was confined to bed. He continued to run a low-grade fever. Other white-cell counts were 13,900 and 19,200.

On the second hospital day an operation was performed.

DIFFERENTIAL DIAGNOSIS

DR. CHANNING C. SIMMONS: There are some data that are not given in the protocol that might be of value in making a diagnosis. The blood chemical findings, for instance, would be of value in ruling out certain bone tumors, and a tuberculin test would help in ruling out tuberculosis of the sacroiliac joint. No mention is made of lymph-node involvement.

DR. BENJAMIN CASTLEMAN: The serum calcium was 9.4 mg. per 100 cc., the phosphorus 4.3 mg., and the phosphatase 1.7 Bodansky units. A tuberculin test was not done.

DR. SIMMONS: In other words the phosphatase was on the low side of normal. The serum protein would be of value in ruling out plasma-cell myeloma, which I doubt that this boy had.

Are the x-ray films available?

DR. LAURENCE L. ROBBINS: These films show a destructive process involving the ilium, with apparent extension up to but not involving the

CASE 30352

PRESENTATION OF CASE

A twelve-year-old schoolboy entered the hospital complaining of pain in the right hip.

The patient had been well until three months before admission, when he slipped and fell on his right hip. He developed pain and limitation of

sacroiliac joint. The soft-tissue mass definitely extends into the pelvis.

DR. SIMMONS: What is the shadow at the hilus of the right lung?

DR. ROBBINS: It is possibly due to enlarged hilar nodes, but I could not be positive without fluoroscoping the patient.

DR. SIMMONS: The physical examination says that the abdomen was negative, and makes no men-

rather than in the body of the bone. I can rule out syphilis on account of the negative Hinton test.

I do not know of any systemic disease that gives an appearance of tumor, with bone destruction limited to one bone, associated with an elevated temperature and white-cell count.

Then there are the tumors. It might have been metastatic from either a tumor of the kidney or a neuroblastoma of the mediastinum or suprarenal

FIGURE 1. Roentgenogram of Pelvis.

tion of what, in the film, is obviously a shadow occupying the greater part of the pelvis.

In all cases of bone disease there are three groups of diseases to consider: first, an inflammatory condition, such as tuberculosis, osteomyelitis or syphilis; second, a systemic disease such as parathyroid or Paget's disease; and, third, some form of bone tumor, benign or malignant and either primary or secondary. I frankly cannot make a definite diagnosis on this boy, but on the basis of the facts given in the protocol and the x-ray findings I have to consider these three conditions.

Of the inflammatory conditions, because of the low-grade temperature, the history of trauma and the bone destruction, he might have had an osteomyelitis. I am not particularly concerned with tuberculosis, since it usually arises around the joint

gland. It might have been a primary bone tumor. An osteogenic sarcoma in this situation is unusual. A Ewing's sarcoma is quite common and often results in a somewhat elevated white-cell count and a low-grade fever. There is one other tumor that can simulate in bone practically every condition that I know, and that is a malignant lymphoma. A lymphoma can cause bone destruction and give a picture like that of osteomyelitis.

I frankly cannot make a diagnosis in this case. I believe that it was probably an osteomyelitis but cannot rule out a lymphoma or a Ewing's sarcoma. I should want a biopsy.

DR. ALLAN M. BUTLER: You would want a biopsy before considering therapy?

DR. SIMMONS: Very definitely. There is no use in giving therapy unless one knows what one is

ating. If it is malignant disease, one can give sufficiently heavy treatment; whereas if it is an inflammatory condition, this method of treatment should not be used. The radiologists are loath to treat any condition by x-ray unless a biopsy has established a diagnosis.

CLINICAL DIAGNOSIS

Osteomyelitis of ilium.

DR. SIMMONS'S DIAGNOSIS

Osteomyelitis of ilium?

Malignant lymphoma?

Ewing's sarcoma of ilium?

ANATOMICAL DIAGNOSIS

Ewing's sarcoma of ilium.

PATHOLOGICAL DISCUSSION

DR. CASTLEMAN: Apparently this mass must have been felt, as Dr. Simmons suggested, because they were able to puncture it with a needle and to aspirate a good-sized biopsy specimen. Microscopically the lesion proved to be a Ewing's sarcoma.

Preoperatively it was believed to be an osteomyelitis because of the sepsis, the high white-cell count and the fever. Following the biopsy the child was given a course of x-ray treatment and sent home. I recently heard from Dr. G. W. Van Gorder, who followed the patient, that within six weeks the child died of diffuse metastases to the lungs. I suppose that the shadow that Dr. Simmons pointed out in the chest film could have been a metastasis. Is that so, Dr. Robbins?

DR. ROBBINS: Probably.

POSTWAR PLANNING

Of the approximately 55,000 medical officers now in military service, 3000 have been asked to express themselves concerning postwar medical training. Of these, 927 had replied up to June 1, and the answers to the questionnaire are reported in the June 24 issue of the *Journal of the American Medical Association*. If this sample is representative of the whole group, — and there is no reason to think that it is not, — a large order in postwar medical education is about to be placed.

Divided according to the dates of licensure, which are roughly parallel to the dates of graduation from the medical school and therefore to age groups, the 927 officers fell into the following groups: Group 1,

400 (43 per cent); Group 2, 323 (35 per cent); Group 3, 168 (18 per cent); and Group 4, 36 cent). Group 1 consisted of those licensed 1937 to 1943; Group 2, those licensed from 1936; Group 3, those licensed from 1920 to 1936; and Group 4, those licensed before 1920.

Of these Group 1 is the largest, and those trained in it are the youngest and the most in of postwar education. Many men in this group had their periods of medical training shortened hurried by the war, so that it is not surprising 90 per cent of them state that they will graduate between one and two years of additional training. If the ratio of 400:927 holds for the 55,000 officers the total number of Group 1 men — those who graduated subsequent to 1936 — will approximate 24,000.

Already about 300 of these 400 officers, or about 18,000 of the total, have stated that they wish to specialize, which means that residencies will be in demand. A previous survey has shown that there are in this country about 8000 residencies, and it was suggested that these facilities might be expanded to accommodate 12,000 in the immediate postwar period.* The necessity for a gradual demobilization is apparent if all the officers wishing training are to be accommodated without preliminary waiting periods, for there will be a greater load than the teaching hospitals of the country can possibly absorb in any one-year or two-year period. The replies of these young medical officers also indicate that rural communities will continue to find it difficult to attract doctors. Only 6 per cent expressed a preference for a rural location, the majority preferring a community of between 25,000 and 250,000 population.

To what extent this thinking on the part of the small sample analyzed represents the whole and to what extent the thinking of the whole may undergo future changes remain to be decided. For the present one can only visualize a postgraduate medical education program of unprecedented proportions — something that will have to bring into use a larger proportion of clinical material than has ever before been utilized.

*Medicine and the war: postwar graduate medical education. A preliminary report by the Council on Medical Education and Hospitals. *J. A. M. A.* 124:40, 1944.

Y IS A JAP?

THE magazine *Time*, although not ordinarily used as a journal of scientific reference, contains in its August 7 issue two items of more than ordinary interest regarding the Japanese behavior pattern. The first is an account by Robert Sherrod, *Time* correspondent, of the mass suicides on Saipan. The second is the news story of an analysis of Japanese character by Geoffrey Gorer, anthropological investigator in the Institute of Human Relations at Yale University.

The western world has become thoroughly accustomed to bizarre stories of the picturesque Japanese *seppuku* ceremony, considering the idea of it as something remote from our own usual mental processes. We know of how, in times of peace, the over-mind Japs were wont to toss themselves into the craters of hyperactive volcanoes; from our marines in the South Pacific and our soldiers on Iwate and Kiska we have more recently heard of the wholesale and apparently purposeless self-destruction practiced by the soldiers of the Emperor when faced with final defeat. This has frequently been not a matter of fighting to the last ditch. Soldiers have impaled themselves on the bayonets of the enemy or have fallen on their own swords or blown themselves to bits with hand grenades when they still had ammunition with which to continue fighting.

On Saipan, for the first time, our forces gained possession of territory with a considerable settled Japanese population, and so prevalent became suicide among the civilians of both sexes and all ages, according to Sherrod, that the question is raised whether the whole Japanese race will choose death to surrender.

Gorer, in his study of Japanese psychology, and with perhaps more than a slight leaning toward the Freudian concept, places great emphasis on the severe toilet training of the Japanese infant. Beginning at the age of four months the baby is held over the balcony or road at frequent intervals and for obvious reasons not at all suggestive of the Capulet and Montague affair. Lapses in conduct are punished with great severity. At six months he is

taught to bow respectfully (although the polite hissing through the teeth is waived), and before the end of the first year "he is forced to learn to sit stiffly on his haunches."

The male is taught that he belongs to the dominant sex, but even so his life is bound rigidly by convention. To overstep a rule of behavior brings ridicule without mercy from friend and foe, and so we find developed the repressions that have their outlet in cruelty and arrogance toward supposedly weaker individuals and races, and the dread of loss of face, which makes life intolerable in an environment that has become hostile.

We thus see in the rigid training of the Japanese both his strength and his weakness. It drives him on through hardship and danger with the endurance of a fanatic, but when it fails to achieve its goal he is finished. If we accept the thesis, however, that the modern Japanese is the product of an unfortunate environment and not a completely strange and different biologic mishap, then there is some hope of adapting future generations of the race to existence in a world that recognizes the rights of others.

MASSACHUSETTS MEDICAL SOCIETY

DEATHS

BROWN — Edison W. Brown, M.D., of Revere, died August 18. He was in his sixty-ninth year.

Dr. Brown received his degree from Tufts College Medical School in 1905. He was a member of the American Medical Association and the New England Obstetrical Society and a staff member of the Chelsea Memorial Hospital, Whidden Memorial Hospital, Everett, and Winthrop Community Hospital.

His widow, his mother and two sisters survive.

COBB — Farrar Cobb, M.D., of Hyannis, died May 28. He was in his seventy-eighth year.

Dr. Cobb received his degree from Harvard Medical School in 1893. He served on the staff of the Massachusetts General Hospital and as superintendent of the Massachusetts Eye and Ear Infirmary. He was chief surgeon from 1930 to 1935 and on the consulting staff from 1930 to 1944 of the Cape Cod Hospital. He was a member of the American Medical Association and the New England Surgical Society and fellow of the American College of Surgeons.

DUNN — Lt. Raymond A. Dunn, of Worcester, was killed when the destroyer on which he was medical officer was sunk by enemy fire in the invasion of Sicily. He was in his thirty-fourth year.

Dr. Dunn received his degree from Tufts College Medical School in 1935. He was an obstetrician on the staff of St. Vincent Hospital. He was a member of the American Medical Association and the Worcester District Medical Society.

His parents, a sister and a niece survive.

CORRESPONDENCE

ANTERIOR POLIOMYELITIS

To the Editor: I have been much interested lately in reading in *Life* the account of the work being done by medical men in North Carolina during the existing epidemic of infantile paralysis.

The statement therein to the effect that these doctors are examining flies in the search for probable means of transmission brings back to my mind very distinctly my experience with that disease in this city some thirty years ago. At that particular time, since I was chairman of the Board of Health, and in contact with the official representative of the State Board of Health, as well as an epidemiologist, I was in a position to see most of the cases of that disease — not only my own patients, but many others; and I was much impressed at the time in observing on the bodies of many of the victims small discolored, concrete areas, which clearly had the appearance of being insect bites.

In my report to the State Board of Health I called attention to this fact. Nothing came of it, however; but I believed at the time, and have believed ever since, that there was to be sought the possible cause of the invasion.

Furthermore, it appeared that shortly before the first cases were reported, — which happened to be my own, — there

were three cases in one locality where a number of pigs in the vicinity all died within a short time; and it was that, before they died, each one was a victim of paralysis. In my opinion this was due to some insect with a very limited radius of activity, as the disease was not general, but confined to certain territories, where the afflicted persons adjacent to one another.

I hope this study in North Carolina will bring forth something worth while.

NOTICES

ANNOUNCEMENT

Dr. Alice Nauen announces the removal of her office from 121 Sutherland Road, Brookline, to 41 Concord Avenue, Cambridge 38.

NEW ENGLAND HOSPITAL FOR WOMEN AND CHILDREN

The monthly clinical conference and meeting of the staff of the New England Hospital for Women and Children will be held on Thursday, September 7, in the classroom of the Nurses' Residence at 7:15 p.m. Dr. Louis K. Diamond will speak on the subject "The Rh Factor." Dr. Hildur Gibs will be chairman.

SOCIETY MEETINGS AND CONFERENCES

CALENDAR OF BOSTON DISTRICT FOR THE WEEK BEGINNING THURSDAY, SEPTEMBER 7

THURSDAY, SEPTEMBER 7

7:15 p.m. The Rh Factor. Dr. Louis K. Diamond. New England Hospital for Women and Children.

SATURDAY, SEPTEMBER 9

*10.00-11.30 a.m. Medical staff rounds. Peter Bent Brigham Hospital.

MONDAY, SEPTEMBER 11

International Association of Industrial Accident Boards. Hotel Statler, Boston.

*12:15-1:15 p.m. Clinicopathological conference. Peter Bent Brigham Hospital.

TUESDAY, SEPTEMBER 12

International Association of Industrial Accident Boards. Hotel Statler, Boston.

*12:15-1:15 p.m. Clinicorontgenological conference. Peter Bent Brigham Hospital.

WEDNESDAY, SEPTEMBER 13

International Association of Industrial Accident Boards. Hotel Statler, Boston.

*12.00 m. Clinicopathological conference. Children's Hospital.

*Open to the medical profession.

PAGET'S DISEASE: ITS PATHOLOGIC PHYSIOLOGY AND THE IMPORTANCE OF THIS IN THE COMPLICATIONS ARISING FROM FRACTURE AND IMMOBILIZATION*

EDWARD C. REIFENSTEIN, JR., M.D.,† AND FULLER ALBRIGHT, M.D.‡

BOSTON

THE purpose of this paper is to call attention to the occurrence of acute atrophy of bone (osteoporosis) as a complication of Paget's disease, and to discuss the seriousness and implications of this situation as illustrated by two case histories. In order to make the subsequent presentation clear, it will be necessary first to discuss briefly normal bone metabolism, the metabolic abnormalities in osteoporosis as opposed to those in osteomalacia and osteitis fibrosa generalisata, the morbid anatomy of Paget's disease and finally a concept concerning the pathologic physiology in Paget's disease. It is regretted that some repetition of previous presentations¹⁻⁴ is unavoidable.

NORMAL BONE METABOLISM

Normal bone is composed of an organic matrix in which is deposited a calcium-phosphate-carbonate salt. It has three types of surface — one on which nothing is happening, one on which bone is being resorbed and one on which bone is being formed (Fig. 1). Where bone is being resorbed, one sees osteoclasts. Bone formation consists of two steps — the laying down of the matrix by osteoblasts and the deposition therein of the calcium salt.

It should be emphasized that bone formation and bone resorption occur at one and the same time. The reason why the body can deposit calcium on one surface while it is being resorbed on another is probably connected with the enzyme phosphatase. It is thought that the enzyme is made by the osteoblasts and that its presence where bone matrix is being formed increases the local concentration of phosphate ions by the splitting off of these ions from organic phosphate compounds, and hence promulgates the deposition of a calcium-phosphate-carbonate salt. In the absence of hepatic disease,

the serum alkaline phosphatase level is an index of the activity of the osteoblasts. In the presence of excessive osteoblastic activity the serum phosphatase level rises; with osteoblastic inactivity it tends to fall. Since the normal level of the serum phosphatase is extremely low, however, this fall is not usually discernible.

There is considerable evidence that stresses and strains strongly stimulate the osteoblasts to lay down bone matrix: the greater the stresses and strains, the greater is the bone formation. Thus, persons whose occupations involve considerable physical activity have heavy skeletons, whereas those with sedentary occupations tend to have light bones.

OSTEOPOROSIS, OSTEOMALACIA AND OSTEITIS FIBROSA GENERALISATA

Osteoporosis, osteomalacia and osteitis fibrosa generalisata have one thing in common, a decreased bone mass. The total bone mass may be diminished to a pathologic degree from either an increase in bone resorption or a decrease in bone formation. The former is called "osteitis fibrosa generalisata" (Fig. 1) and is found in hyperparathyroidism. As will be seen later, it has certain points in common with Paget's disease. A decrease in bone formation may result either from an underactivity of the osteoblasts in laying down bone matrix or from a failure in the deposition of calcium salts in this matrix: the former is termed "osteoporosis," and the latter "osteomalacia" (Fig. 1).

Since the cases to be reported represent, in the final analysis, the imposition of osteoporosis on Paget's disease, it is desirable to discuss this condition in more detail. The causes of osteoporosis include old age, lack of stresses and strains to stimulate the osteoblasts, — for example, immobilization,³ — lack of estrin to stimulate the osteoblasts — for example, postmenopausal osteoporosis^{1,2} — and lack of protein to provide material for the matrix, such as is found, according to our conception, in

FIGURE 1. Schematic Diagrams Showing the Differences in Bone Metabolism between Normal, Osteoporosis, Osteomalacia and Osteitis Fibrosa Generalisata Complicating Hyperparathyroidism (reproduced by permission of the Journal of the American Medical Association).

In all the diagrams, the designations are as follows: A — body limits; B — body fluid, C — body serum, a compartment of body fluid easy to tap for analysis; D — bone mass with two surfaces, one where bone is being resorbed and one where it is being laid down; E — arrow indicating by its size the rate of calcium and phosphorus resorption; F — osteoclast; G — rate of calcium and phosphorus deposition; H — osteoblast laying down osteoid (I); J — calcium and phosphorus entering the gastrointestinal tract; K — calcium and phosphorus leaving the body by the kidneys and other exits; L — syringe for obtaining serum for analysis; M — blood values (N, normal; +, high; and —, low).

NORMAL. Note that the deposition of calcium and phosphorus (G) equals the resorption (E) and that part of the latter goes back into the bone.

OSTEOPOROSIS. Note the decrease in bone mass (D₁), the primary hyperplasia of osteoblasts (H₁), the decreased deposition of osteoid (I₁), the decreased deposition of calcium and phosphorus (G₁), the increased excretion of calcium and phosphorus (K₁) and the normal blood values (M₁).

OSTEOMALACIA. Note the decrease in bone mass (D₂), the hyperplasia of osteoblasts (H₂) because of increased stresses and strains, the increased deposition of osteoid (I₂) inadequately calcified because of the low serum calcium and phosphorus values, the decreased deposition of calcium and phosphorus (G₂), the primary difficulty in absorbing calcium and phosphorus from the gastrointestinal tract (J₂) and the abnormal blood values (M₂).

OSTEITIS FIBROSA GENERALISATA COMPLICATING HYPERPARATHYROIDISM. Note the increased excretion of calcium and phosphorus in the urine (K₃), the increased resorption of calcium and phosphorus (E₃), the increase of osteoclasts (F₃), the decreased bone mass (D₃), the increased bone formation by osteoblasts (I₃) because of increased stresses and strains, the increased deposition of calcium and phosphorus (G₃) because the serum is not undersaturated in respect to calcium phosphate, and the high phosphatase level (M₃).

Cushing's syndrome,^{4,5} in the osteopathies of starvation and probably in the demineralization associated with hyperthyroidism.

Osteoporosis being by definition primarily a disorder of tissue metabolism and only secondarily one of calcium metabolism, no alteration in the serum calcium and phosphorus levels is to be expected, nor is one usually found. Since in osteoporosis bone formation decreases and bone resorption continues unabated, however, hypercalciuria occurs, and may lead to the same kidney complications as are found in hyperparathyroidism, in which the hypercalciuria results from the hypercalcemia.

The degree of hypercalciuria — the diet being constant — depends on the discrepancy between bone destruction and bone formation. If osteoporosis develops gradually, this discrepancy is at no time great and hypercalciuria is not marked. If, on the other hand, bone formation suddenly stops in a nonosteoporotic skeleton, there is marked hypercalciuria — for example, artificial menopause or immobilization of the skeleton in a cast. Furthermore, in young subjects, in whom the turnover of bone is more prominent than in older ones, a sudden curtailment of bone formation results in a marked imbalance.

There was recently reported from this laboratory³ the case history of an active fourteen-year-old boy who fractured his leg and had a large part of his skeleton immobilized by a cast. So great was the resulting decrease in bone formation that not only hypercalciuria but also hypercalcemia occurred. The cause of the latter was an inability of the kidney to excrete the calcium as rapidly as it came from the skeleton. Since the hypercalcemia suggested hyperparathyroidism, the patient was subjected to two operations in an effort to find a parathyroid tumor before the true situation became apparent. The hypercalcemia soon disappeared when he was mobilized. The cases reported below illustrate another situation in which a serious state from acute atrophy of disuse (osteoporosis) occurred.

MORBID ANATOMY OF PAGET'S DISEASE

If one defines a "localized bone disease" as any disease that is not generalized, Paget's disease is localized. It may be limited to one bone or be widely spread throughout many bones, but it is not generalized. One can almost invariably find somewhere a sharp line of demarcation between normal bone on one side and Paget's disease on the other. The very fact that Paget's disease is not generalized is strong evidence against its being a metabolic or endocrinologic disorder. The reader may well ask, "What about the bone cysts in hyperparathyroidism?" But these are secondary complications; the underlying lesion, decalcification, is generalized. The reader may then ask, "What about postmenopausal osteoporosis, in which the bone

lesions tend to be confined to the spine and pelvis?" Here the disease is following a well-defined pattern; certain parts of the skeleton are more prone to involvement than others and the distribution of the lesions is not spotty but according to plan; it is not as though the twelfth thoracic and third

FIGURE 2. Photomicrographs of the Bone in Paget's Disease (A) and Hyperparathyroidism (B).

Note that although the osteoclasts (Oc.) and the osteoblasts (Ob.) are present in both diseases the structural integrity has disappeared in A but is maintained in B. Note also the mosaic appearance of the cement lines, some of which are indicated by arrows. (These photographs were kindly supplied by Dr. Granville A. Bennett, to whom the authors are greatly indebted.)

lumbar vertebrae were involved whereas the remaining vertebrae were normal.

Having made the above rather dogmatic statement, we must make one reservation. We have in our clinic a patient with undoubted Paget's disease in whom every bone in the body is involved; moreover, each bone is at the same stage of the disease. Unfortunately, the patient refuses to be hospitalized for detailed studies.

When one comes to the actual bone lesion in Paget's disease, it has much in common with that seen in osteitis fibrosa generalisata (compare Fig. 2A and B). In both conditions the bone lesions are extremely vascular, there is marked fibrosis, about half the bone surface is covered with osteoclasts as evidence of marked bone resorption and about half with osteoblasts as evidence of marked bone repair, and the bone that is being laid down

FIGURE 3 Photographs Showing That the Initial Lesion in Paget's Disease is Bone Destruction.

A — the x-ray film of a skull with two areas of destruction separated by a bridge of normal bone (between the arrows). B — the x-ray film of the same skull post mortem. C — the skull as it appeared post mortem. D — a section through this skull showing the advancing edge of destruction (arrow), with normal bone to the right and involved bone to the left. E — a photomicrograph of the area at the point of the arrow in D, showing normal bone on the right and the initial lesion of bone destruction on the left with osteoclasts (arrow) in juxtaposition to the normal bone.

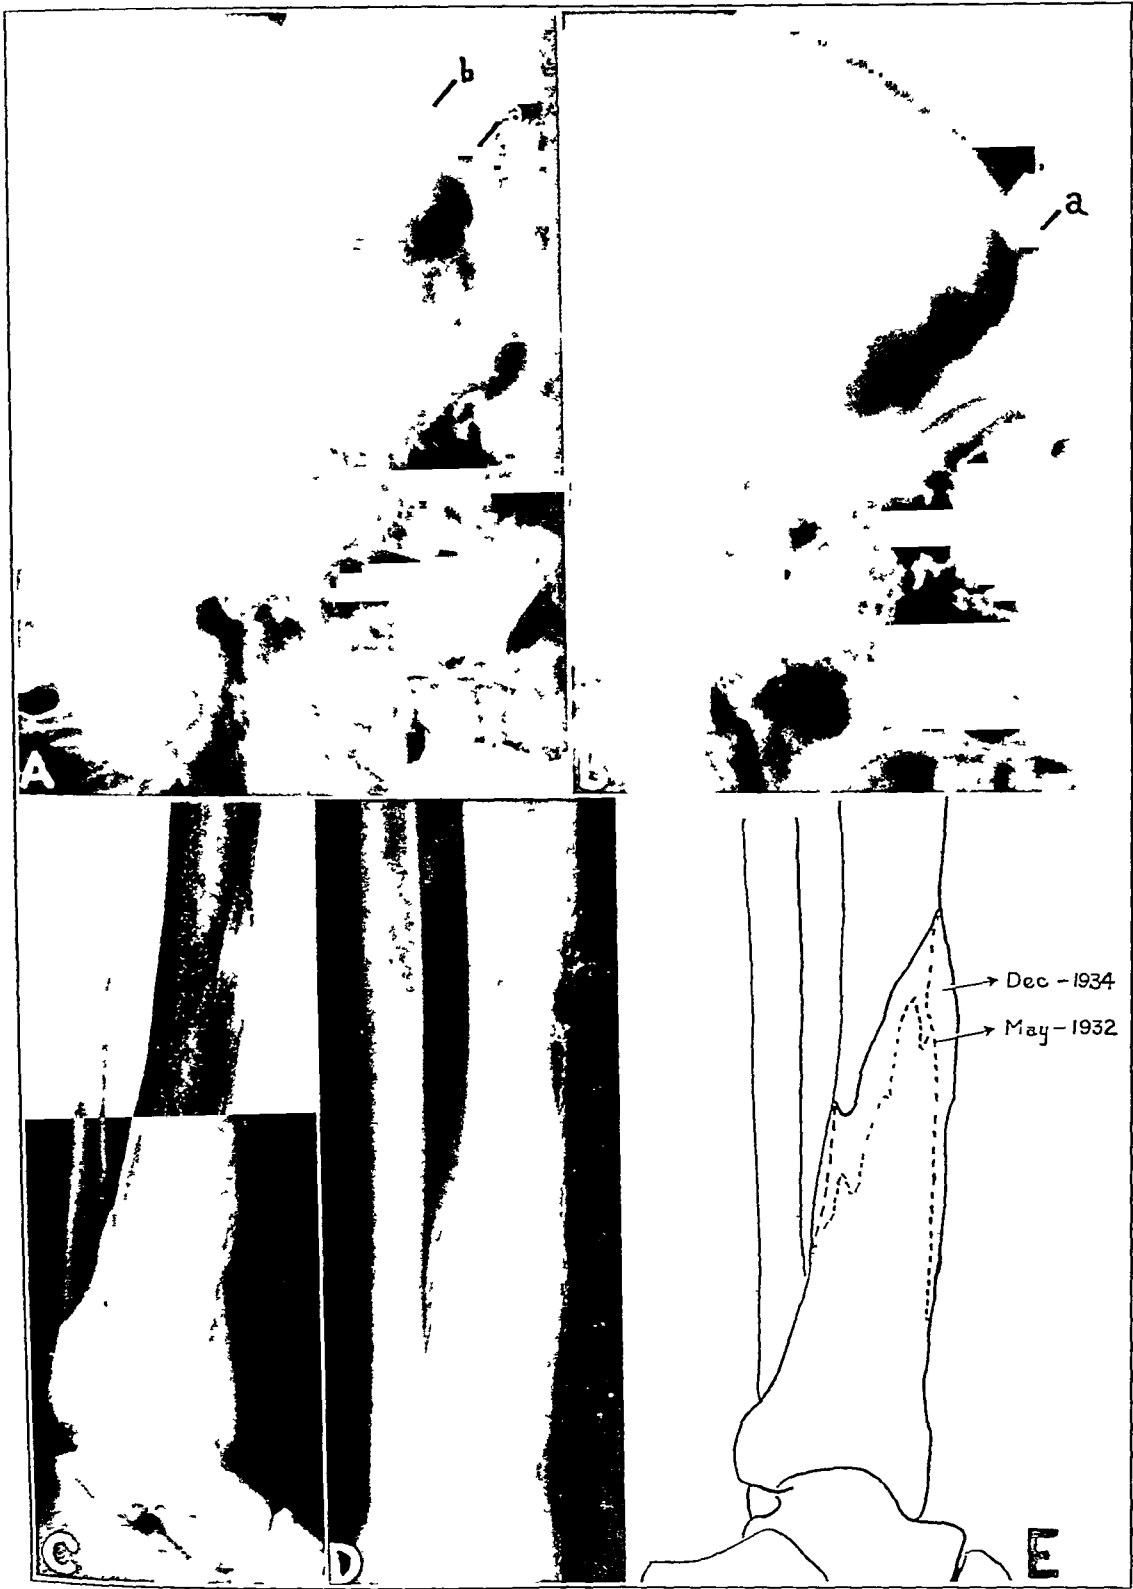

FIGURE 4 The Progression of Paget's Disease

A — skull showing an area of destruction (a to b) and normal bone to the right and overgrown bone to the left. B — the same skull two years later showing that the area of destruction has moved closer to the nose. C — involvement of the tibia. D — same tibia two and a half years later. E — diagram indicating the progression of the lesion in the tibia.

is being calcified, as shown by the normal width of the osteoid seams. There are, however, some differences. There is not the same tendency to the formation of so-called "osteoclastomas" or brown tumors in Paget's disease as in osteitis fibrosa generalisata. The most important distinction between the two conditions, however, concerns the architecture of the bone. In Paget's disease, for reasons that will appear below, the trabeculae start nowhere and end nowhere; in osteitis fibrosa generalisata there may be extreme decalcification, but those trabeculae that are left are in good mechan-

what is going on in a complicated pathologic picture, one should always try to get at the advancing edge of the lesion and see what comes first.

In the skull in Paget's disease one often finds lesions that have quite a different appearance from those encountered in other parts of the skeleton. They lack the marked overgrowth of bone and consist merely of circumscribed areas of bone destruction. The x-ray appearance of such a lesion is shown in Figure 3A. The involved area terminates abruptly (see arrows). At autopsy, a section through such an area (Fig. 3D) showed normal

FIGURE 5. X-ray Films of Paget's Disease (Case 1), Showing the Right Femur Immediately (A), Fourteen Weeks (B) and Seven Months (C) after the Fracture. Compare the densities of the cortex at the points indicated by the arrows.

ical arrangement. A third difference between the two conditions has to do with the so-called "mosaic structure," as first described by Schmorl.⁶ This pathognomonic feature of Paget's disease is due to the bizarre arrangement of the cement lines within the trabeculae (see arrows in Fig. 2). To be sure, there are other bone diseases with an increased number of cement lines in the trabeculae, but the lines are not so completely irregular. The reason for them will be discussed below.

From the above discussion, it is evident that in Paget's disease there is a marked increase in both bone destruction and bone formation; in other words, there is an increased turnover of bone. If one had to guess, one would presumably suppose that the increased bone formation was the result of increased bone destruction. But one does not have to guess; one can examine the initial lesion. To discover

bone (to the right of the arrow) sharply demarcated from the involved bone (to the left of the arrow). A microscopic examination at this point (Fig. 3E) revealed normal bone (to the right) being destroyed by the destructive lesion (to the left), with numerous osteoclasts; no bone formation or osteoblasts were seen. This is strong evidence that the initial lesion in Paget's disease is bone destruction.

Support for this contention can be derived from the characteristic manner in which the disease progresses. Thus, x-ray films of an involved skull (Fig. 4A) show three zones: normal bone (to the right of a), bone destruction (a to b) and bone repair with overgrowth and increased density (to the left of b). If such an area of involvement is followed for several years, the zone of bone destruction in some cases may be seen to advance. Such was the case in this skull, in which the lesion advanced into

the normal bone closer to the nose (Fig. 4B). In the long bones, for reasons that will appear below, the bone repair usually occurs almost simultaneously with the bone destruction, and one seldom has the opportunity to see one process divorced from the other; occasionally, where one does (Fig. 4C, D and E) the same sequence of zones appears. Schmorl⁶ demonstrated that the initial lesion in the long

of albumin. The sediment contained no casts, a rare red cell and 15 white cells per high-power field.

The leg was placed in traction, with a Kirschner wire through the lower end of the femur and a Hodgson splint with a Pierson attachment. The patient was allowed to take as much milk as he desired. He remained comfortable for 2 weeks, but then he began to complain of anorexia, headache and peculiar sensations of dryness in the back of the throat, associated with difficulty in swallowing. The patient attributed these symptoms to his "chronic sinusitis"; an otolaryngologist considered this probable, although he

bones is also bone resorption. He did this by making a longitudinal section of an involved long bone, from which he took a cross section 2 cm. distal to the point where the bone was involved grossly enough to be detectable by the naked eye. This cross section showed bone destruction without any evidence of bone formation.

CASE REPORTS

CASE 1* (M. G. H. 316138). The patient, a 58-year-old salesman, was admitted to the Phillips House on August 14, 1941. At the age of 22 he was aware of bowing of the left tibia. At the age of 28 he stepped into a hole and fractured the left tibia. X-ray examination revealed Paget's disease in the area of the fracture. This break healed without incident. At the age of 52 he fell down a flight of stairs and fractured the neck of the right femur. X-ray examination showed that this break also had been through an area of Paget's disease. The bones healed poorly, and finally a plate was inserted. Eight months after the fall, the patient was allowed to get about on crutches. He again fell and fractured the right femur in nearly the same place. He was placed in traction for 7 weeks and then in a plaster cast for 8 weeks. Eventually he was able to walk without crutches. On the day of admission, he was involved in an automobile accident, and for the third time fractured the neck of the right femur (Fig. 5A).

The past history revealed several interesting points. For many years the patient had consumed a large amount of milk—between 5 and 5 glasses a day. In his travels as a salesman, he had been in the habit of stopping for a milkshake several times a day, and in addition he had drunk milk at each meal. Also from time to time he had taken excessive amounts of alkalis for gastric distress. For more than 20 years he had been troubled with so-called "chronic sinusitis," with postnasal discharge and pain in the cheekbones.

Urinalysis shortly after admission showed a clear specimen with a pH of 5.0, a specific gravity of 1.028 and a slight trace

could find little on examination, and advised spraying the throat. The patient obtained no relief from this, but began to have epigastric distress, nausea and occasional vomiting. Urine examination at this time showed a specific gravity of

FIGURE 6. Chart Illustrating the Effect of Fracture on the Serum Calcium, Phosphorus and Phosphatase Levels in Paget's Disease (Case 1).

1.01, no albumin, a rare red cell and 2 white cells per high-power field. The serum nonprotein nitrogen was 56 mg. per 100 cc.

On September 10, 1941, approximately 4 weeks after the fracture, the serum calcium was 13.4 mg. per 100 cc., the serum phosphorus 4.2 mg., and the serum phosphatase 4.3 Bodansky units. These studies were repeated 2 weeks later with essentially similar findings (Fig. 6 and Table 1). At that

*This patient was seen through the courtesy of Dr. O. S. Staples and Dr. T. A. Warthin.

time the nonprotein nitrogen was 68 mg per 100 cc. A urine concentration test showed that the specific gravity was fixed at 1.008, but a phenolsulfonephthalein test showed 20 per cent of the dye excreted in 15 minutes. During the next 3 weeks

was permanently stopped and the intake of other fluids was increased. Within 1 week the patient was feeling much better. The serum calcium was 10.3 mg per 100 cc, the phosphorus 3.6 mg, and the phosphatase 6.1 Bodansky units.

FIGURE 7 X-ray Films of Paget's Disease (Case 2), Showing the Right Femur three years before (A) immediately (B), three weeks (C), five weeks (D) and ten weeks (E) after fracture. The point of fracture is indicated by the arrow. Compare the densities of the cortex in these films.

the patient continued to have gastric distress. The water intake was increased and milk was omitted from the diet for several days, the serum findings were as follows: calcium, 12.2 mg per 100 cc, phosphorus, 4.0 mg, protein, 6.4 gm, and nonprotein nitrogen, 36 mg.

On October 30, because of our concept regarding the pathologic physiology of Paget's disease (see below), the milk

He was able to concentrate his urine to a specific gravity of 1.017. Thereafter he had an uneventful convalescence, except that the fracture healed very slowly. He was discharged July 11, 1942, 11 months after admission.

CASE 2 (M G H 281615) The patient, a 64-year-old woman, was admitted to the hospital on December 28, 1942,

with a fractured femur. At the age of 50 she became aware of enlargement of the head and the left clavicle. X-ray examination revealed Paget's disease. At the age of 57 she noticed bowing of the femurs. For some years she had been troubled with increasing deafness and ringing in the ears. She had never passed gravel. A physiologic menopause without hot flashes had occurred at the age of 52. In June, 1939, she was referred to one of us (F.A.) by Dr. Louis Hamman, of Baltimore.

The x-ray films of the femurs obtained in 1939 (Fig. 7A) had been used for teaching purposes to explain why it is possible in Paget's disease for a bowed leg to be as long as, if

FIGURE 8. *Paget's Disease Showing Fracture through the Site of a Previous Infraction.*

Other infractions above and below the fracture are indicated by arrows

not longer than, the unbowed leg. (The question was raised and answered by Schmorl.⁶) It will be seen that a series of partial fractures occurred on the convex side that led to an increase in length of a fraction of a centimeter for each fracture. It can be appreciated that it would not be difficult to produce a complete fracture at one of these points. The site at which the fracture subsequently developed is indicated by the arrow. (That this is not an isolated occurrence is shown by an x-ray film of another case [Fig. 8], in which fracture occurred through one of the points of partial separation. Other points of infraction are indicated by the arrows.)

Physical examination in June, 1939, revealed the typical picture of Paget's disease, with great enlargement of the head, marked overgrowth of the jaws and enlargement of the left clavicle and both femurs. The blood pressure was 155/95. There were present a basal systolic murmur and a thrill that were interpreted as aortic stenosis on an arteriosclerotic basis. The serum calcium level was 10 mg. per 100 cc. The urine contained a moderate amount of calcium, and the sediment showed 10 to 15 white cells per high-power field.

The patient was advised to take 1 glass of milk and 10 drops of viosterol three times a day. She was seen at about

yearly intervals thereafter. The blood-chemistry findings at these visits are given in Figure 9 and Table 2. In November, 1941, a urine examination showed a specific gravity of 1.030, no albumin, a moderate amount of calcium and 20 to 30 red cells and 4 to 6 white cells per high-power field. At that time the milk intake was reduced to 2 glasses a day and the viosterol intake was decreased to 10 drops twice a day. In addition, sodium citrate, 2 gm. three times a day, was prescribed.

On November 19, 1942, the urine showed a specific gravity of 1.002, no albumin and 2 red cells and 4 white cells per high-power field. The serum calcium was 10.4 mg. per 100 cc., the serum phosphorus 4.0 mg. and the serum phosphatase 28.0 Bodansky units.

On December 28, the patient slipped on the floor and fractured her right femur at the junction of the middle and distal third. She was admitted to the Baker Memorial Hospital under the care of Dr. George W. Van Gorder.* X-ray examination showed the fracture fragments to be in satisfactory alignment; hence no orthopedic procedures were instituted except simple traction (Fig. 7B).

The course thereafter is shown in Figure 9 and Table 2. Because of the experience in Case 1, milk was omitted from the diet from the time of admission, and other fluids by mouth were forced so far as possible. The patient remained comfortable for the first 5 weeks. Then, as the serum calcium began to rise, she complained of anorexia and dryness in the nose and throat, with difficulty in swallowing. This was followed by constant nausea and vomiting. The fluid intake became inadequate. For the next 3 weeks, during the period of maximal hypercalcemia, the patient was given almost daily an intravenous infusion of 1000 to 2000 cc. of equal parts of 5 per cent dextrose and normal saline solutions. On February 8, 1943, when the serum calcium level had fallen to 11.1 mg. per 100 cc., the intravenous infusions were discontinued. At the same time the gastric and pharyngeal symptoms practically disappeared, and thereafter the patient was able to maintain an adequate fluid intake by mouth.

X-ray films taken on January 18, 1943 (Fig. 7C), 21 days after the fracture, showed that the alignment had been maintained and that a marked amount of calcified callus was already present. The bone healed so rapidly that by the first week in February the traction could be removed, and by February 15 the patient was able to get out of bed. The subsequent course was uneventful.

DISCUSSION

Pathologic Physiology of Paget's Disease

The pathologic lesions of Paget's disease have been discussed; it remains to attempt an interpretation. It is clear that the initial lesion is a localized factor causing bone destruction, which has no respect for structural requirements. The bone destruction renders the involved bone more susceptible to stresses and strains. To compensate for this, the osteoblasts are stimulated to lay down more matrix; the serum phosphatase level — an index of osteoblastic activity — therefore rises. When the stresses and strains are constantly present (in the vertebrae and long bones), bone repair occurs almost simultaneously with bone destruction; when stresses and strains are minimal, as in the skull, bone repair may lag behind bone destruction (see above).

In the meantime, the localized destructive factor persists and continues to destroy bone, including some that has been newly laid down as a reparative process. The joints between new and old bone are

*We are indebted to Dr. Van Gorder for his co-operation in the study of this patient.

marked by cement lines; in the constant battle between bone destruction and bone repair many such lines arise. Since the local destructive factor has no respect for the mechanical requirements of the skeleton, the lines have no order, hence the mosaic structure (see arrows in Fig. 2A). There results a bone of poor architectural value. This factor explains three of the striking clinical characteristics of the disease: the marked tendency to overgrowth of bone, the fact that the serum phos-

patients herein cited showed hypercalcemia and some evidence of decreased renal function.

Case 2 illustrates well the sequelae of immobilization in a patient with Paget's disease. The serum phosphatase fell from 42 to a low of 13 Bodansky units; the serum calcium gradually climbed from 10.1 to a high of 13.9 mg. per 100 cc., this high point coinciding with the low point on the phosphatase curve. The daily calcium excretion in the urine reached 519 mg. When activity was resumed the

FIGURE 9. Chart Illustrating the Effect of Fracture on the Serum Calcium, Phosphorus and Phosphatase Levels and on the Urinary Excretion of Calcium and 17-Ketosteroids in Paget's Disease (Case 2).

phatase level, — an index of bone repair, — is so high per unit of diseased bone and the tendency of bones to become deformed in spite of marked overgrowth — for example, bowed femurs.

In Figure 10 the sequence of events is illustrated schematically.

Effect of Immobilization on Paget's Disease

When a bone containing Paget's disease is immobilized, the stimulus for bone formation ceases; and bone destruction continues unabated. There results a decrease in the serum phosphatase level and in bone mass and an increase in the urinary excretion of calcium (Fig. 10B). There may even be hypercalcemia when the amount of calcium to be excreted exceeds the ability of the kidney to excrete it (Fig. 9) or when the kidney function becomes impaired from hypercalciuria. Thus, both

values returned to the prefracture levels, the daily calcium excretion in the urine falling to 38 mg.

Possible Role of the Alarm Reaction

The decreased formation of bone in Case 2 was probably not entirely due to immobilization. As with any injury,⁷ there was a depression of the urinary 17-ketosteroid excretion, with a return to a normal value for a patient of this age with recovery — from 1.7 mg. in twenty-four hours on the third day after injury to 5.5 mg. on the seventy-seventh day. It is quite probable that not only this change in the 17-ketosteroid excretion but also part of the depression in bone formation are to be attributed to an alteration of adrenocortical function that is common to all injuries (compare the so-called "alarm reaction" of Selye⁸). The net result of this altered function following injury is a

curtailment of tissue formation except at the site of injury.⁵ Ordinarily such a curtailment may be overlooked, but in Paget's disease, where bone formation is rapid and extensive, any influence that suppresses it is magnified.

It should be noted that this curtailment of tissue anabolism following injuries does not affect the

good callus was being put down at the site of the injury.

Dangers and Their Prevention

When a patient with Paget's disease is immobilized, the danger of a so-called "chemical death" exists. Thus, the patient in Case 2, if treated in

FIGURE 10. Schematic Diagrams Showing the Processes in Uncomplicated Paget's Disease (A) and in Paget's Disease after Immobilization (B).

Three stages or zones are depicted: I, normal bone; II, bone destruction; III, bone destruction with compensatory repair.

UNCOMPLICATED PAGET'S DISEASE. The designations are as follows: A — body limits; B — body fluid; C — bone mass having three surfaces (one where nothing is happening, one where bone is being resorbed, and one where it is being laid down), D — osteoblast laying down a matrix of osteoid tissue (E); F — arrow indicating by its size the rate of deposition of calcium and phosphorus; G — osteoclast; H — arrow indicating by its size the rate of resorption of calcium and phosphorus; I — calcium and phosphorus entering the body through the gastrointestinal tract; J — calcium and phosphorus leaving the body by the kidneys and other exits; K — arrow indicating the direction of advancement of the disease process. In Zone II, note the decrease of the bone mass, the increase of osteoclasts and the increase in the rate of resorption of calcium and phosphorus. In Zone III, note that the increased stresses and strains from the decreased bone mass in Zone II have resulted in an increase of osteoblasts, an increase in the rate of deposition of calcium and phosphorus and an increase in bone mass, which is of poor quality. Analyses of the serum (L) show a normal calcium level, a slightly elevated phosphorus level and a markedly elevated phosphatase level.

PAGET'S DISEASE AFTER IMMOBILIZATION. The osteoblasts (D_i) are hypoplastic owing to loss of the stimulus of stresses and strains through immobilization; this results in a decrease of matrix (E_i) and a decrease in the deposition of calcium and phosphorus (F_i). In Zone III note that the huge amount of compensatory bone formation (F) is no longer present because of immobilization. Since bone destruction (H) continues unabated, there results not only a marked diminution of the bone mass (C) but also a tremendous increase in the excretion of calcium and phosphorus in the urine (J_i). Analyses of the serum (L_i) show a markedly elevated calcium level, a slightly elevated phosphorus level and a phosphatase level that is still slightly elevated.

anabolism at the site of the injury. It is not unlikely that there is some local factor that causes maximal tissue repair there. Thus in Case 2, while the rest of the femur was melting away, a

the ordinary fashion with liberal amounts of milk, no special regard for fluid intake and more than minimal immobilization, might well have developed an even higher blood calcium level, anuria and

death. Metastatic calcification in the lungs might have been overlooked at autopsy and the cause of death put down as bronchopneumonia. To control the hypercalcemia and hypercalciuria, all that is needed is a low-calcium diet and sufficient fluid by vein if need be so that the serum and urinary calcium concentrations do not rise to dangerous levels. Immobilization should be kept at the absolute minimum, and mobilization should be begun as early as possible, not only to avoid chemical death but to avoid extreme atrophy of the bones (Fig. 5C).

A Possible New Symptom of Hypercalcemia

Besides nausea and vomiting, which are recognized symptoms of hypercalcemia, both the patients herein cited experienced a peculiar sensation of dryness in the nose and throat, with difficulty in swallowing. These symptoms seemed to be associated with the hypercalcemia. The patient in Case 1 was treated for "sinusitis" for several weeks before the probable role of the hypercalcemia in producing these symptoms was appreciated.

SUMMARY AND CONCLUSIONS

The bone lesions of Paget's disease are not generalized but spotty in their distribution. This fact alone is strong evidence against the disturbance being on an endocrinologic or metabolic basis.

The initial lesion in Paget's disease is bone destruction, the cause of this being entirely obscure. The resultant weakness of the involved bones renders them less resistant to stresses and strains, and this leads to a stimulation of the osteoblasts and an overproduction of bone. In the skull, where there are fewer stresses and strains, one frequently encounters bone destruction divorced from the overproduction of bone (so-called "acute Paget's disease of the skull").

The repair of bone by the osteoblasts is never completed, since the localized initial disorder causing bone destruction apparently persists. There results alternating destruction and repair of bone, which eventually leads to the pathognomonic pathological finding, the so-called "mosaic structure." This mosaic appearance is due to the highly irregular cement lines, each one of which demarcates a place where bone destruction temporarily ceased and bone repair began.

The increased bone destruction and bone repair seen in the lesions of Paget's disease are closely

similar to those seen throughout the skeleton in the osteitis fibrosa generalisata of hyperparathyroidism. There is one important difference, however: in osteitis fibrosa generalisata, that bone is destroyed that can best be spared; in Paget's disease, bone is destroyed without regard to structure. This accounts for the complete lack of arrangement in the cement lines (see above), and for the fact that the bones in Paget's disease are extremely pliable in spite of marked overgrowth of bone.

If a bone containing Paget's disease is immobilized as after a fracture, the following events occur: A lack of stress and strain, in all probability abetted by the alarm reaction of Selye, curbs the overactivity of the osteoblasts, and the serum phosphatase level, an index of bone formation, falls. The initial disturbance causing bone destruction persists. There results a marked imbalance between bone destruction and bone formation. The increased calcium and phosphorus coming from the bone leads to hypercalciuria and hyperphosphaturia. The capacity of the kidney to excrete calcium may be overtaxed, with a resulting hypercalcemia; if fluids are not forced, if the diet is not kept low in calcium and if immobilization is not kept at a minimum, a so-called "chemical death" from hypercalcemia may supervene.

Studies are cited of 2 patients with Paget's disease who sustained fractures. The above chain of events, up to and including the hypercalcemic stage, took place.

Although, in Paget's disease, the broken bone becomes decalcified as a whole, the fracture site shows a rapidly forming and calcifying callus. This is best explained by the hypothesis that some local influence stimulating osteoblasts is set loose at the site of the fracture.

EOSINOPHILIC INFILTRATION OF THE LUNGS (LOEFFLER'S SYNDROME)*

STEWART H. JONES, M.D.,† AND CARLTON R. SOUDERS, M.D.‡

BOSTON

IN the differential diagnosis of pulmonary disease Loeffler's syndrome should be remembered. It has been mistaken for tuberculosis,¹ bronchiectasis and neoplasm, and probably explains many so-

and the fatigue for 2 months. The cough was only slightly productive, was worse at night than in the daytime, and was associated with sufficient wheezing so that ephedrine had been prescribed. At times she had a sharp pain of short duration in the right side of the lower thorax, and a "tired feeling" in the lumbar region. She had had similar, but milder, attacks each autumn for the preceding 2 years, but had not felt ill enough to consult a physician.

On physical examination the patient was found to be underweight but did not appear to be ill. The only significant signs were in the upper lobe of the left lung, where the resonance was impaired and sibilant rales were present.

Roentgenograms of the chest showed an infiltration extending out from a large left hilar shadow into the mid-lung and reaching the periphery in the second intercostal space anteriorly (Fig. 1). A pneumonic consolidation or neoplasm was suspected. Examination of the lungs by fluoroscopy suggested the possibility of tuberculosis.

Hematologic examination revealed a marked eosinophilia, which with other findings is shown in Table 1. Hemoglobin determinations, red-cell counts and urine analyses were normal. To discover a possible cause of the eosinophilia the following tests, the reactions to all of which were negative, were done: sputum examination for tubercle bacilli, a patch test with tuberculin, the giving of eighteen inhalant and food allergens endermically, examination of two warm stools for amebae and ova, agglutination tests for brucellosis,

FIGURE 1. Roentgenogram of Chest Taken October 21.

called "abortive" pneumonias, as well as the frequent infiltrations seen in roentgenograms of the lungs of patients with bronchial asthma.

Loeffler² first described this condition in 1932 and presented 37 cases. Since then a small number of cases has been reported, both in children and in adults, by various authors in many languages. A recent fluoroscopic examination of 6283 men discharged from Army service revealed abnormalities of the lungs in 55.³ In 13 of these the diagnosis was eosinophilic infiltration.

CASE REPORT

A 33-year-old, married Negress came to the Lahey Clinic on October 21, 1943, complaining of cough and fatigue. She had always lived in the vicinity of Boston, and worked as a private secretary. The cough had been present for 2 weeks

FIGURE 2. Roentgenogram of Chest Taken October 27

and an intracutaneous test with brucellergin (0.1 cc, undiluted), and an intracutaneous test for trichinosis.

The patient continued to rest at home, but was not ill enough to remain in bed. On October 27, a roentgenogram showed some diminution in the lung shadow (Fig. 2), and by December 7 the shadow had completely disappeared (Fig. 3). At that time she no longer coughed, had gained

†Member, Department of Internal Medicine, Lahey Clinic.
‡Member, Department of Internal Medicine, Lahey Clinic (on leave of absence).

3 pounds in weight and felt well enough to return to work. On examination a month later, no abnormal signs or symptoms were present.

DISCUSSION

Since no deaths as a result of Loeffler's syndrome have been reported, the nature of the pathologic

FIGURE 3. Roentgenogram of Chest Taken December 7

changes that occur in the pulmonary tissues is unknown. Its cause is likewise unknown, although allergy is suspected from its frequent association with vasomotor rhinitis and asthma and its occasional occurrence in persons with an allergic family

parasites, such as *Fasciola hepatica* and *Ascaris lumbricoides*, have been found.^{4,6} A seasonal incidence of this disease was recorded in China by Engel⁷ who found that cases occurred during May and June while the privet plant was pollinating. Loeffler's cases occurred in July and August. That allergy to the tubercle bacillus may be the cause has been suggested, but Loeffler found positive tuberculin tests in only 13 of 37 adults, and only 1 of these subjects subsequently developed tuberculosis. Smith⁸ has reported a case of Loeffler's disease followed by severe asthmatic symptoms.

A possible relation with brucellosis has been suggested in two cases⁹ in which there were pulmonary infiltrations accompanied by an eosinophilia and definite evidence of brucellosis.

Eosinophilia thus tends to favor the allergic hypothesis. Ten to 60 per cent of the leukocytes are usually eosinophils, and often the highest count is reached when the infiltration is disappearing. Eosinophilia may persist for variable periods,¹⁰ and in one patient lasted for nine months. There is no parallelism between the degree of pulmonary infiltration and the eosinophil count. Eosinophilia is not essential for making the diagnosis, since it may be absent or be depressed by associated infection. More important for diagnosis are concomitant allergic manifestations.

The patient frequently complains of a metallic taste, cough, wheezing and malaise. He does not feel or appear ill. The temperature may be slightly elevated; diminished resonance with sibilant rales may be heard over the areas of consolidation, and blood examination may show leukocytosis, eosinophilia and an increased rate of sedimentation of the erythrocytes. In contrast to the paucity of signs and symptoms are the roentgenographic changes.

Breton¹² described the shadows in the roentgenograms of the lungs as appearing rapidly, disappearing in three to eight days and reappearing elsewhere in the lungs. Fine star-shaped scars were said to

TABLE 1 Summary of Data

1/ 5/44	6,300	9.0	41.0	0.0	40.0	10.0	0.0	15.0

background. Various substances have been considered as allergens. In one patient¹ symptoms and roentgenographic findings persisted for four months until amebae were eliminated from the stool. Another patient⁵ had amebae in the sputum but not in the stool, and both the lung infiltration and the accompanying asthma disappeared after emetine therapy. Other

result. Loeffler¹ observed the pulmonary densities to be single or multiple, unilateral or bilateral, and clearly or irregularly outlined, and in some cases to be indistinguishable from pulmonary tuberculosis.

SUMMARY

A case of Loeffler's syndrome has been presented with a discussion of its significance, cause, symp-

toms and diagnosis. As possible causes the following were considered and rejected: tuberculosis, infestation with amebae or other intestinal parasite, brucellosis and trichinosis. The syndrome appears to be a manifestation of allergy, the cause of which is unknown.

PENICILLIN SODIUM THERAPY IN EXPERIMENTAL WEIL'S DISEASE*

DONALD L. AUGUSTINE, Sc.D.,† DAVID WEINMAN, M.D.,‡ AND JOAN McALLISTER, M.A.§

BOSTON

REPORTS from different sources¹⁻³ have conclusively shown the value of penicillin in the treatment of relapsing fever and rat-bite fever in animals. Its remarkable therapeutic value in these two spirochetal diseases suggested that similar action of the drug could be expected in the treatment of infectious jaundice. The following experiments were performed to gain information on this question.

Our strain of *Leptospira icterohaemorrhagiae* was obtained in January, 1944, from Dr. Martin Frobisher of the Johns Hopkins University School of Hygiene and Public Health. It had been freshly isolated from a human infection and was highly virulent for guinea pigs. Prior to the present experiments it was maintained for several weeks in our laboratory by passage in guinea pigs. The infected animals usually developed jaundice on the fourth to the sixth day and died before the seventh day after infection. White guinea pigs, weighing approximately 180 gm each, were used for the tests. The penicillin sodium was furnished by Dr. Chester S. Keefer. Two experiments were performed.

Experiment 1 Ten guinea pigs were inoculated intraperitoneally with 1 cc of a suspension of macerated livers and kidneys from other infected animals. Dark-field examinations showed the inoculum to be rich with spirochetes. On the fourth day after infection the entire lot showed varying degrees of jaundice. Five animals in which jaundice was particularly pronounced were selected for treatment. The remaining 5 guinea pigs served as controls. The treated animals received intraperitoneally 4000 Oxford units of penicillin in 1 cc of saline solution every four hours for seventy-eight hours, or until death occurred.

The first death was that of one of the treated guinea pigs, which had received 4000 units of penicillin. Two more of the treated animals died after having received 8000 units of the drug, and the remaining 2 treated animals were

found dead on the morning following the last treatment or after having received the total dose of 48,000 units. All the untreated controls died prior to the death of the 2 guinea pigs that received 48,000 units of the drug. At autopsy, both treated and untreated animals showed similar and characteristic lesions, with motile leptospira in fresh preparations of the liver and kidneys.

From the results obtained from this experiment it appeared that either penicillin was inactive against *L. icterohaemorrhagiae* or that the disease had progressed to such an extent before treatment was begun that any action the drug might have had against the organism did not alter the course of the disease.

Experiment 2 Eight guinea pigs were inoculated with *L. icterohaemorrhagiae*, as in the previous experiment, but treatment was begun before objective symptoms of the disease became apparent. Thirty-eight hours after the inoculations were made, treatment of 4 of the animals was instituted. Each of the treated animals received intraperitoneally 5000 units of penicillin sodium in 1 cc of saline solution every four hours for forty-eight hours. The total dose received by each guinea pig was 60,000 units.

Jaundice was evident on the third day of infection in all the untreated controls. Three of the controls died, one on the third and two on the seventh day after inoculation. At autopsy these animals showed characteristic lesions of Weil's disease. The fourth control, which appeared to have recovered, was sacrificed on the fifteenth day after inoculation. The internal organs appeared normal. No spirochetes were found in several fresh specimens of the liver, lungs and spleen, but a few were seen in preparations of the kidneys.

None of the treated animals developed apparent jaundice or other signs of illness except slight roughness of fur. One of the animals was found dead on the morning of the fourth day after completion of the treatment. Another was found dead on the fifth day, and a third died on the seventh day after final treatment. Thus, deaths among the treated lot of guinea pigs occurred on the eighth, ninth and eleventh days after inoculation. At autopsy *L. icterohaemorrhagiae* was demonstrated in the liver and kidneys of each of these guinea pigs, but there were no severe lesions. The roughness of fur on the last guinea pig was of a transient nature, and by the tenth day after inoculation it appeared normal. It was sacrificed on the eleventh day after final treatment, or the fifteenth day after infection. All organs appeared normal. No spirochetes were seen in several fresh preparations of the liver, kidney, lungs and spleen.

§Assistant in comparative pathology and tropical medicine, Harvard School of Public Health.

In this experiment there is evidence that penicillin had some suppressive effect but was not curative.

The results of a series of experiments by Hamre et al.⁴ show that the acute toxicity of penicillin in guinea pigs, mice and rabbits is low; however, daily dosages of 7000 to 12,000 units per kilogram of body weight given subcutaneously over a period of several days caused the death of guinea pigs but not that of mice or rabbits. When guinea pigs were treated with the same dose of penicillin per kilogram as that given to man, they did not die and failed to show any signs of toxicity. It is therefore possible that the death of the treated guinea pigs was due to toxicity of the drug rather than to the experimental infection. The fact that the treated animals in the second experiment did not die until four to seven days after treatment had been stopped indicates that the drug was not the cause of death.

* * *

Our findings are not in accord with those of Heilman and Herrell,⁵ who report no deaths from the disease in 32 guinea pigs treated with penicillin and a mortality rate of 91 per cent in an equal number of untreated controls. This difference may be attributed to the early administration of peni-

cillin — seventeen to twenty-four hours after inoculation — and to the use of a strain of *L. icterohaemorrhagiae* with relatively low virulence.

From these results it is apparent that penicillin has a suppressive effect on the organism in a highly susceptible host when given before the appearance of clinical manifestations. This observation suggests that the early use of penicillin might alleviate the symptoms of Weil's disease in man, in whom the disease has a relatively low fatality rate. The value of penicillin in practice, however, is questioned. Its early administration might be effective in preventing the disease, but in the present experiments, it had no curative value after the appearance of clinical manifestations.

Correction. In the article "Phenarsine Hydrochloride in the Treatment of Syphilis" by Drs. W. F. Boardman and R. Kaldeck, which appeared in the January 6, 1944, issue of the *Journal*, the figures given in Table 2 for the dosage of phenarsine are erroneous. The "thousands" represent the number of doses, and the "hundreds" the dosage in milligrams. In other words, in Case 1 six doses totaling 200 mg. were given, in Case 2, seven doses totaling 300 mg. and so forth.

MEDICAL PROGRESS

THORACIC SURGERY

JOHN W. STRIEDER, M.D.*

BOSTON

THE publication of this review during the sixth year of the war finds many of the world's outstanding thoracic surgeons in the armed forces of their respective countries, and an increasing proportion of a diminishing literature concerned with the surgery of trauma and of war.

Surgery has been called the child of trauma, and it is generally considered that the experiences gained in World War I furnished the impetus that resulted in the precocious development of thoracic surgery, the youngest child of surgery, during the ensuing quarter of a century. Undoubtedly much that will be learned of the surgery of trauma of the chest in this war will be valuable in the highly mechanized peacetime that lies ahead. Even now, for example, there is a better understanding of the principles involved in the treatment of so commonplace a complication as traumatic hemothorax and its sequelae.

There remains, however, a considerable body of literature that deals with the problems of civilian practice, many of which, as is the case in pulmonary tuberculosis, will be greatly augmented by the ravages of war. Other problems, such as bronchogenic carcinoma, are of increasing importance simply because they are integrated with the natural history of the human race. It is with these and other similar aspects of thoracic surgery that this review concerns itself.

TUBERCULOSIS

Lobectomy

Within very recent years, and with the perfection of the technics of lobectomy and pneumonectomy, many thoracic surgeons who deal with pulmonary tuberculosis have manifested a renewed interest in the application of these procedures to the surgical treatment of this disease.

During the early developmental period of the surgical treatment of phthisis, the actual removal of that portion of a lung containing tuberculous lesions was considered an attractive possibility by various clinicians. Thus, Alexander¹ states that Tuffier performed such an operation in 1891; an indurated tuberculous area in an upper lobe was resected through an incision in the anterior second intercostal space. Seven years later the patient was apparently cured but died of grippe. Up to 1921, however, Tuffier and Jessen had collected less than a dozen cases in which tuberculous pulmonary tissue had been successfully removed, and

about as many in which the operation was fatal or otherwise unsuccessful.

In 1935, Freedlander² reported a case in which he performed lobectomy for a persistent cavity in the right upper lobe. The patient was alive and well as reported by him³ in May, 1944. In 1939, Jones and Dolley⁴ reported two cases of lobectomy and two pneumonectomies for pulmonary tuberculosis. All the patients survived the operations. These results were considered encouraging. In 1940, Dolley and Jones⁵ reviewed their previously reported cases and added 3 more. In the discussion of this paper many surgeons added small series of cases in the aggregate of which the over-all mortality was discouraging. Thus, of 19 patients treated by total pneumonectomy, 8 (40 per cent) died and of 31 treated by lobectomy 8 (26 per cent) died. In 1942, Thornton and Adams⁶ collected and analyzed the reported cases of lobectomy and pneumonectomy. There were 29 cases of pneumonectomy with a mortality of 45 per cent and only 41 per cent satisfactory results. There were 46 cases of lobectomy with a mortality of 26 per cent and 69 per cent satisfactory results. It may be presumed that the majority of the operations were performed by the tourniquet technic. In this series, the most frequent complications were persistent fistula, contralateral spread and empyema. The most frequent indications were tuberculoma, tuberculous bronchiectasis, bronchial stenosis and the persistence of a cavity after thoracoplasty.

It is of interest to note that during this period of discouragement, and at the same meeting of the American Association for Thoracic Surgery in 1940 at which Dolley and Jones reviewed their results, Blades and Kent⁷ reported 10 successful cases of lobectomy for nontuberculous disease (9 of bronchiectasis and 1 of mixed tumor of the bronchus) in which were employed the technic of intrahilar dissection and individual treatment of each hilar structure of the lobe. This splendid contribution followed closely on the pioneer work of Rienhoff⁸ on pneumonectomy for malignant disease by individual ligation and of Crafoord,⁹ Churchill,¹⁰ and Churchill and Belsey,¹¹ the last paper offering new theories of segmental pneumonectomy that had hitherto been only vaguely conceived. It is reasonable to say, then, that a new era in the treatment of pulmonary disease had been entered on.

Up to that time surgical extirpation of the lung or one of its lobes had been accomplished by the use of a tourniquet with mass ligation of the hilar portion of the lung or lobe, as performed by Haight¹² and Graham.¹³ Later, after the manner of Shen-

*Assistant professor of thoracic surgery, Boston University School of Medicine; visiting surgeon in charge of thoracic surgery, Massachusetts Memorial Hospitals; visiting surgeon for thoracic surgery, Boston City Hospital.

stone and Janes,¹⁴ who employed a snare threaded with cord to control the hilus of the lobe, the remaining pedicle after amputation of the lobe could be made smaller and hemostasis effected by placing sutures in the presenting cut surface. Shenstone and Janes performed their lobectomies in one stage, as had Brunn¹⁵ in 1929, when he reported 6 cases with 1 death. This technic, although a milestone in the progress of the attack on the problem, was at best unsatisfactory and unsurgical, since it left masses of devitalized and necrotic tissue in the pleural cavity. Moreover, in the case of pulmonary tuberculosis, tuberculous foci were of necessity traversed during the resection of the pulmonary tissue, with the almost inevitable sequelae of tuberculous empyema or bronchopleural fistula and mixed-infection empyema. Frequently the patient was left with a chronic draining chest sinus, secretions from which were often laden with tubercle bacilli. With the spontaneous opening of a bronchopleural fistula during the postoperative course, bronchogenic spread of the disease in the same or the contralateral lung was of a high order of frequency.

With the proved value of the individual ligation technic, the incidence of these hazards was reduced. In most cases it was no longer necessary to transect tuberculous foci or to leave masses of devitalized tissue to serve as a source of infection within the pleural cavity. The hilar vessels could be individually ligated, forestalling postoperative hemorrhage, and the bronchus closed primarily and covered with pleura or buried in surrounding vital tissue, obviating to a large extent the frequently fatal complication of bronchopleural fistula. Moreover, the hilus of the tuberculous lung was found to be relatively free of the fibrosis that is present in suppurative disease, and the intrahilar dissection could be carried out with comparative ease.

In 1943, Churchill and Klopstock¹⁶ reported 6 cases of pulmonary tuberculosis in which modern lobectomy had been performed. All the patients survived the operation and were either well or greatly improved at the time of the publication of the report. These authors make it clear that they propose lobectomy as a highly selective measure for dealing with certain unilobar lesions. They believe it to be far more conservative of pulmonary function than is even a seven-rib thoracoplasty. Since, however, lobectomy is by definition irreversible, it can be suggested as an alternate to artificial pneumothorax only when tuberculosis has produced irreversible or irreparable destruction of lung substance.

In 3 of these cases, lobectomy was performed as a definitive operation where, up to that time, thoracoplasty might have been the operation of choice. In one of the patients, a twenty-two-year-old woman, tuberculin tests (1:50,000 and 1:20,000 dilutions of old tuberculin) were negative one month after operation. In view of the fact that pulmonary

tuberculosis is generally considered to have bilateral dissemination, even though microscopic, the implications of such a result could be significant only if many similar cases should be reported and stronger doses of tuberculin be used. Although the total eradication of all foci has been the will-o'-the-wisp pursued by phthisiologists ever since tuberculosis of the lung was recognized as an entity, its accomplishment by surgical means will in most cases probably be purely fortuitous.

At the twenty-fifth annual meeting of the American Association for Thoracic Surgery in May, 1944, several papers were presented that evoked considerable discussion of this important aspect of the surgical treatment of pulmonary tuberculosis. There were many technical issues involved that need not be reported here. Janes¹⁷ analyzed the data in 16 cases of lobectomy that he had performed since September, 1941. The most frequent indication was an open cavity with positive sputum. The upper lobe was affected in 7 cases, the middle lobe in 1, and the lower lobe in 9. Three patients (19 per cent) had died at the time of the report and 13 were considered clinically well. All these operations were performed by the dissection technic. Maier and Klopstock¹⁸ reported on 16 cases of lobectomy for pulmonary tuberculosis. There was 1 death, a mortality of 6 per cent. This death occurred one month postoperatively and was due to a tuberculous spread in the contralateral lung. Of the 15 living patients, 12 had a negative sputum at the time of the report. These authors laid particular stress on the necessity for excellent intratracheal anesthesia, meticulous operative technic and precise localization of the lesions.

Twenty-three cases in which lobectomy was performed — with two operations in 1 case — were analyzed by Overholt and Wilson¹⁹ in a paper read before the 1944 meeting of the American Trudeau Society. There was 1 death, a mortality of 4 per cent. Five patients (21 per cent) had ipsilateral or contralateral spreads or ipsilateral exacerbation of their disease. There were 21 living patients of the 22 whom the authors classified as "reasonable risks"; and in these cases the prognosis was considered good in 13 (62 per cent), guarded in 7 (33 per cent), and poor in 1 (5 per cent).

Although Chamberlain²⁰ agrees that there is a place for lobectomy in the treatment of pulmonary tuberculosis, he presents his arguments why he believes that modern selective thoracoplasty with its low mortality (2 to 5 per cent) and high rate of sputum conversion (80 per cent) should be the procedure of choice in disease of the upper lobe. He believes that lobectomy should be performed only after failure of thoracoplasty because in his opinion based on bronchspirometric studies, "primary upper lobectomy" excises only the active major focus, thus causing overdilatation of the remaining lobe, which is probably a precursor of emphysema,

may cause reactivation of latent foci in the overdistended lobes, and leaves these foci in a poor state of healing or self-protection.

Maier²¹ takes issue with this point of view. He has been unable to demonstrate serious impairment of respiratory function of the remaining lobe or lobes by bronchspirometric studies, and believes that true emphysema of functional significance does not occur in the remaining lobe. Apparently progressive lowering of the oxygen-consumption curves does not occur.

It can thus be seen that there is considerable difference of opinion regarding primary upper lobectomy as a definitive operation. Thoracoplasty is an operation of known potential and mortality, whereas there is no imposing array of statistics dealing with lobectomy performed in cases in which, up to now, thoracoplasty might have been considered the operation of choice. Until such time as there is a sufficient number of cases to be of statistical significance, and until enough time — possibly five years — has elapsed to evaluate properly the results — any detailed discussion must be regarded as largely philosophical. Certainly, the use of lobectomy in well-selected cases should be continued. The hazard that the procedure will be carried out indiscriminately to achieve rapidly the prestige of numbers, as has happened all too often in the history of the surgical treatment of tuberculosis, is ever present, and should be guarded against with great fortitude so that the procedure will not be condemned before it has had a carefully controlled trial.

But although at the present time it seems that primary lobectomy of the upper lobe is far from the philosopher's stone in the treatment of pulmonary tuberculosis, there are other indications for lobectomy that appear to be fairly well defined but concerning which there is lack of complete accord among phthisiologists and thoracic surgeons. From my own experience with 14 cases — 7 lobectomies and 7 pneumonectomies — and that of others,¹⁶⁻¹⁹ these indications appear to include tuberculoma, tuberculous bronchiectasis, certain tension cavities, particularly of the lower lobe, stenotic lesions of lobar bronchi and residual cavitation when thoracoplasty has failed.

Pneumonectomy

The problem of pneumonectomy in tuberculosis differs radically from that of lobectomy. Churchill and Klopstock¹⁶ state:

Total pneumonectomy cannot be considered an alternative to collapse therapy provided that collapse therapy is applicable to the case under consideration. It is both irreversible and nonselective. It irrevocably and seriously limits any therapeutic procedure that may be needed for the lung of the contralateral side. Circumscribed by strict indications, total pneumonectomy in tuberculosis may be a life-saving operation when no other operation is feasible.

Since total pneumonectomy is in most cases performed with greater facility for technical reasons than is lobectomy, there is undoubtedly a tendency to abandon the former, if planned in a given case, and to resort to the latter when the original lobectomy if persevered in might have been successfully completed. This has obscured the issue in many cases and rendered the evaluation of results even more difficult, since the indication for pneumonectomy did not originally exist.

The most frequent indication for total pneumonectomy in tuberculosis is partial or complete stenosis of the main-stem bronchus, with or without symptoms of obstruction as manifested by toxemia. Thus, Lorge and Dufault,²² reporting 3 cases from the Rutland State Sanatorium, state that in 2 the indication was stenosis of the stem bronchus and that in 1 there was widespread bronchial involvement with clinical evidence of repeated blockage of secretions. There was 1 death, and 1 patient had a not very active lesion in the contralateral lung that appeared six months later but showed evidence of clearing.

Of the 15 total pneumonectomies reported by Janes,¹⁷ 10 were performed for stenosis and in 7 of these there was an uncomplicated recovery. Other indications were tuberculoma, extensive infiltration of the whole lung with cavitation and hemorrhage, and cavitation of the middle lobe with infiltration to the upper and lower lobes. In the total series there were 3 deaths (20 per cent), 10 patients were considered well or fairly well, and in 2 cases the outlook was unfavorable.

In the series of 36 pneumonectomies reported by Overholt and Wilson¹⁹ there were 6 deaths, a mortality of 17 per cent. The authors divide their cases into "desperate risks," of which there were 11 with 5 deaths (45 per cent), and "reasonable risks," of which there were 25 with 2 deaths (8 per cent). In the total series there was a contralateral spread in 4 cases (11 per cent). In 29 of the cases pneumonectomy was performed for extensive multilobar disease that was predominantly unilateral, in 5 for uncontrolled disease following thoracoplasty, in 1 for basal tuberculosis, and in 1 for extensive disease of the upper lobe found at operation to involve the lower lobe as well. There is no detailed analysis of the present status of the entire series, but of the 23 living "reasonable-risk" patients the prognosis was considered good in 18 (78 per cent), guarded in 3 (13 per cent) and poor in 2 (9 per cent).

At the Massachusetts Memorial Hospitals, pneumonectomy has been performed in 7 cases of tuberculosis. The indications were as follows: stenosis of the main bronchus in 2 cases, extensive unilateral disease in which other measures had failed in 3, pneumothorax failure with an unexpandable lung in 1 and pneumothorax failure with the cavity in the lower lobe reopened after three years in 1. There were 3 deaths (43 per cent), all in the group with

extensive unilateral disease, from nontuberculous pneumonia in the remaining lung, surgical shock and extensive tuberculous contralateral spread, respectively.

Alexander²³ states:

The choice between thoracoplasty and pneumonectomy must be based on a number of important factors. If the bronchial stenosis is so great that the patient cannot effectively evacuate the pulmonary secretions by coughing even after attempted bronchoscopic dilatation of the stricture, and consequently becomes increasingly toxic, thoracoplasty would be unduly dangerous because it probably would, at least during the period of the staged operations, further impair the effectiveness of coughing. In such cases, pneumonectomy is the operation of choice and should also be considered if thoracoplasty has already been performed and has left the patient with the symptoms just mentioned. But if there are any active tuberculous lesions in the opposite lung, or if any progressive ulcerative bronchial lesions are present, pneumonectomy is definitely contraindicated. In this event, no surgical treatment, unless possibly direct surgical drainage of a single large tuberculous cavity, could safely be used. There are very few patients who have the clear-cut indications for pneumonectomy and, at the same time, no contraindication.

This sound opinion is probably the one held by the great majority of thoracic surgeons. Although the presence of bronchial stricture undoubtedly makes thoracoplasty more hazardous, Alexander, Sommer and Ehler²⁴ report that 25 patients (66 per cent) in a series of 38 cases have closed cavities and negative sputums and that only 3 (8 per cent) are dead.

As is the case in lobectomy, only time and a careful follow-up will permit an accurate evaluation of the place of pneumonectomy in the treatment of pulmonary tuberculosis.

BRONCHOGENIC CARCINOMA

The increasing frequency with which cancer of the lung has been reported as a cause of death in recent years has aroused considerable speculation whether the increase represents a real change in the incidence of this form of malignant neoplasm or is merely the result of improved methods of diagnosis in combination with a more careful search for a disease that has attracted attention because it is reported more frequently than it has been in the past. Dorn²⁵ states that between 1914 and 1930 the death rate from cancer of the lungs and pleura increased by nearly 400 per cent, as compared with an increase of 20 per cent for all forms of cancer combined. The change among males exceeded that among females, the respective increases being 450 and 260 per cent.

The death rate from cancer of the lungs and pleura continued to increase from 1930 to 1940. Eliminating the changes in the age composition during the past decade, this death rate is shown to have increased by 22 per cent among white females and by 78 per cent among white males, or roughly 2.5 and 8.5 per cent per year, respectively. Nearly 3 per cent of 39,970 patients with malignant neoplasm in the white population of a

study group were reported to have a primary cancer of the lung.

It is estimated that between 450,000 and 500,000 persons in the United States are under treatment for cancer. In approximately 20,000 of the known cases there is a primary cancer of the respiratory system; of these patients about 13,000 are being treated for primary cancer of the lung. Slightly more than 8000 new cases of primary cancer of the lung are diagnosed and receive treatment for the first time each year.

Ochsner and DeBakey²⁶ state that at the beginning of this century the lesion was considered a museum curiosity, but that recently it has been shown that the lung ranks second only to the stomach as the primary site of cancer. This statement is in accord with a ten-year survey of autopsies on carcinoma of the lung by Halpert²⁷ at the Charity Hospital in New Orleans, which reveals both a relative and an absolute increase. During the decade ending December 31, 1940, 12,972 autopsies were performed, 8862 of them on persons over one year of age. Among the subjects there were 135 with carcinoma of the lung, 205 with carcinoma of the stomach, and 66 each with carcinoma of the biliary system and of the pancreas. A year-by-year analysis shows that whereas the incidence of carcinoma of the stomach remained about the same, that of the lung gradually increased and during the last two years *exceeded* that of carcinoma of the stomach.

Blades²⁸ states that at the Barnes Hospital in St. Louis 62 proved cases of bronchogenic carcinoma were seen from 1933 to 1936. During the following three years, 117 patients with bronchogenic carcinoma were admitted for treatment. It thus becomes apparent that the increase in the incidence cannot be attributed to improvements in diagnosis or increased awareness of the condition, but must be considered actual, as demonstrated both by autopsy and by clinical observations.

Although bronchogenic carcinoma occurs most frequently in the age group of fifty to seventy, no age is exempt. It is seen frequently in the thirties and forties, and Hauser²⁹ reports a case in a Negro baby aged seventeen months.

To my knowledge, there has never been an authenticated case of bronchogenic cancer that has been reported as a five-year cure as the result of radiation therapy. Many radiologists,^{30, 31} however, believe that this form of therapy has palliative usefulness and should be employed in certain inoperable cases.

It is now generally recognized that the ideal in the treatment of bronchogenic carcinoma is its surgical extirpation by total pneumonectomy. In rare cases lobectomy may be used, but, as in cancer surgery in general, only by the sacrifice of the entire organ can one hope to achieve the greatest number of cures. Since Graham's¹³ first successful

case in 1933, hundreds of successful pneumonectomies have been performed in the various thoracic clinics throughout the world.

Unfortunately, the vast majority of cases in which this diagnosis is made are inoperable when first seen by the thoracic surgeon. Thus, of 155 cases of primary carcinoma of the lung seen by Churchill³² only 27 (17 per cent) were suitable for resection. In a recent three-week period, I saw 18 patients with proved bronchogenic cancers, only 1 of whom was operable when first seen and on whom pneumonectomy was successfully performed. During 1941 to 1943, approximately 75 cases were diagnosed and 50 proved histologically at the Boston City Hospital and Massachusetts Memorial Hospitals. Of these only 7 (9 per cent) were operable. Overholt³³ found 26 per cent of his cases to be operable. It may therefore be assumed that somewhere between 10 and 25 per cent of cases are operable when first considered for surgery, a sad reflection on the ability of physicians to recognize this relatively frequent disease in its early and favorable stages.

The contraindications for pneumonectomy, which in most cases constitute the reasons for inoperability and as a corollary mean a late diagnosis and advanced disease, are based on certain findings. These have been summarized by Graham³⁴ as follows:

The presence of bloody pleural fluid. This usually means invasion of the visceral and parietal pleura by the growth. In most cases, the presence of clear effusions also means inoperability, and the finding of tumor cells in such effusions makes it certain.

Paralysis of the corresponding half of the diaphragm, as determined by fluoroscopic examination. This usually is evidence of invasion of the phrenic nerve.

Paralysis of the left vocal cord in cases of left-sided bronchogenic carcinoma. This usually denotes invasion of the left recurrent nerve as it passes under the arch of the aorta.

Severe pain in the thoracic wall or down the arm. This is a bad sign and generally is evidence of an involvement of intercostal nerves or of the brachial plexus. The presence of a moderate amount of pain, however, should not preclude an exploratory operation.

Bronchoscopic evidence of extension of the tumor into the trachea. This usually contraindicates pneumonectomy, although occasionally it is possible to remove even a part of the wall of the trachea.

The presence of distant metastases. In exceptional cases it may prove justifiable to remove both the lung and a solitary metastasis.

The question of the age of the patient is important from the standpoint of operability, but at least up to the present time there is no fixed limit. The general condition, and particularly that of the cardiovascular apparatus is more important than the chronological age. (Graham's oldest patient

to survive was sixty-eight; another patient of seventy years made an immediately satisfactory recovery but died suddenly of coronary thrombosis one week later.)

In view of the frequency of the occurrence of the disease and its insidious character in the early stages, only a concerted effort, together with the acquisition of a nation-wide state of awareness to bronchogenic cancer on the part of the medical profession as a whole, will result in early diagnosis for a greater number of patients afflicted with this disease and a consequent improvement of the chances for cure.

Any male patient of middle age or beyond who develops cough and expectoration, with or without hemoptysis or blood streaking, and who cannot be shown to have tubercle bacilli in the sputum should be considered to have bronchogenic carcinoma until it is proved unequivocally that there is some other reason for his symptoms.

The first step leading to diagnosis is, of course, a roentgenogram of the chest. In most cases this simple procedure suggests the diagnosis either by indirect evidence, such as atelectasis of a lobe or lobes due to an obstructive bronchial lesion, or by the more positive evidence of an infiltrative hilar lesion or parenchymal tumor. Alexander³⁵ states that despite the prevailing impression, most *circumscribed* intrathoracic neoplasms are intrapulmonary and malignant. All pulmonary abscesses and suppurative lesions should be considered as resulting from bronchogenic carcinoma. In general, one may say that the roentgenogram shows the tumor, which may be relatively tiny, less frequently than its result, which usually predominates in the clinical picture. In rare cases the roentgenogram is negative. In any event, the second step is almost always bronchoscopy, by which a positive diagnosis before operation can best be made. In Graham's³⁴ experience a positive diagnosis can be made by bronchoscopic biopsy in about 75 per cent of cases. Holinger and Radner³⁶ state that in Jackson's series a diagnosis by biopsy was possible in 75 per cent of cases of bronchial cancer, and that Kramer and Som obtained a positive tissue diagnosis in 74 per cent of cases and Clerf in 68 per cent.

The problem of what advice to give in the 25 per cent of cases without a positive diagnosis is an important one. In Graham's³⁴ opinion, the answer is generally fairly simple. If there is a reasonable suspicion of carcinoma, an exploratory thoracotomy should be performed without delay, for in this way many lives can be saved. Too often the advice of the physician has been to wait to see if anything happens. Nothing is gained by this delay, and the usual result is another victim.

An analysis of the risks involved in pneumonectomy reveals an encouraging trend for an operation that must be considered to be technically still in its

developmental stage. In 1940, seven years after the first successful pneumonectomy for bronchogenic cancer, Churchill³² reported hospital deaths in 14 (67 per cent) of 21 patients undergoing total pneumonectomy. Fifteen of the 27 patients subjected to resection — lobectomy and pneumonectomy — died in the hospital, and 7 died subsequently of their disease. At the time of the report, 5 of 155 patients with proved primary carcinoma were alive with no apparent residual or recurrent disease. Churchill finds these results to be similar to those reported by Edwards, who noted a salvage of 6 patients out of a total of 172 cases. In 1940, Samson and Holman³⁷ reported 5 cases with 4 recoveries, and in the same year, Ochsner and DeBakey³⁸ reported 19 cases with 10 recoveries. In 1941, Overholt³³ reported 31 cases with 9 operative deaths (29 per cent). Graham³⁴ reports that in the last 25 cases of pneumonectomy performed by him and Blades there were only 3 deaths, a mortality of 12 per cent.

Graham further discusses the question. Shall the thoracic surgeon offer a chance, even though a small one, to the bad-risk victim of bronchogenic carcinoma, or shall he decline to operate because of the great danger of an operative mortality? He believes that most thoracic surgeons offer the patient a chance of recovery. A mortality of 12 per cent in 25 cases is a respectable one, and should dispel the all too widespread belief that the operation of total pneumonectomy for primary cancer carries with it an enormous operative risk. It should be remembered that without operation the risk is 100 per cent.

BRONCHIECTASIS

It is now generally agreed that the definitive treatment of bronchiectasis is surgical, and that most patients in whom it is discovered should be considered for lobectomy or pneumonectomy, although many may, after evaluation, be denied operation for a variety of reasons.

Corroboration of this statement is obtained in several recent studies, one of the best of which is presented by Perry and King.³⁹ Basing their conclusions on a follow-up of 400 patients, these authors show that in a twelve-year study the mortality in the nonsurgically treated cases was 26 per cent, 41 per cent of these patients dying within five years of onset and 15 per cent living twenty years or longer after onset. Of the patients who died, 78 per cent died directly from their disease. Some statistical evidence supports the view that patients who develop bronchiectasis before the age of ten do not live beyond the age of forty. Thus, of persons with the onset in the first decade only 9 per cent were living at the age of forty or over. Of the 59 patients who reached the age of forty or over, in only 15 per cent was the onset in the first decade. The operative mortality in one hundred and twenty-two

modern-type lobectomies performed on 116 patients (by Churchill at the Massachusetts General Hospital) was 3 per cent. The working and living capacity of the traced living patients was considered to be excellent in 67 per cent of the surgical group and 38 per cent of the nonsurgical group. These authors find nonsurgical treatment to be only palliative and believe that because of the steadily decreasing operative mortality rate, simple lobectomy may be advised without hesitation. Even with bilateral disease the risk in bilateral lobectomy — of course in two stages — is often not too great.

Bradshaw, Putney and Clerf⁴⁰ studied 242 patients with bronchiectasis. Of these 112 were living and 59 died from bronchiectasis or its complications.

Riggins⁴¹ found the mortality for 85 patients with medically treated bronchiectasis collected during ten years with many observed for only three or four years, to be 14 per cent. He concludes, "The morbidity and mortality of untreated and medically treated bronchiectasis . . . is such that the physician who routinely advises young adults with operable bronchiectasis against surgery, is assuming a grave responsibility and in all probability renders his patient a great disservice." It should be added that children stand thoracic operations exceptionally well, and lobectomy early in life is almost certain to obviate the hazards of bronchiectasis that such children must face if they grow to adolescence or adult life with nonsurgical treatment.

Averaging the figures given by various students of the disease, Hinshaw and Schmidt⁴² estimate that less than 10 per cent of patients with severe bronchiectasis obtain a satisfactory result from any form of medical treatment, and conclude that the mortality rate within ten or fifteen years after the diagnosis is made is somewhere between 30 and 50 per cent. When severe bronchiectasis appears in childhood, it is improbable that the patient will live beyond the age of forty years.

The development of the modern technic⁷ of intrahilar dissection and individual ligation has further improved the operation of lobectomy as applied to bronchiectasis. Although occasionally not feasible or even impossible in cases of so-called "frozen hilus" owing to dense fibrosis resulting from repeated exacerbations of pneumonitis, this technic materially reduces the postoperative complications of empyema and bronchopleural fistula already alluded to in the section on lobectomy in tuberculosis. The advent and increasing availability of penicillin promises a further reduction in the incidence of postoperative empyema. At the Massachusetts Memorial and Boston City hospitals it has already been used prophylactically, in a few cases both intrapleurally and intramuscularly, as part of the postoperative routine, with gratifying results. It is still too soon, however, to draw any definite conclusions.

Additions to the knowledge of the surgical anatomy of the detailed structure of the lung, refinements in bronchography and clinical experience have demonstrated that a lobe of the lung is actually made up of a cluster of bronchopulmonary segments. In this connection an important contribution was made by Churchill and Belsey¹¹ in 1939. They correctly prophesied that the bronchopulmonary segment would replace the lobe as the surgical unit of the lung. Although it had been suggested by Nelson⁴³ in 1934 that the lungs are made up of eight lobes—two upper lobes, two middle lobes, the dorsal divisions of the lower lobes and the basal divisions of the lower lobes—it remained for these surgeons to demonstrate the actual clinical application of such an anatomic configuration. They applied the principle of segmental pneumonectomy to resection of the lingula of the left upper lobe—left middle lobe—by removing the posteromedial segment of the lingula, and also employed the technic in operations on the dorsal divisions of the lower lobes. In a recent paper, Blades⁴⁴ describes a technic for other partial excisions, for example, of the basal division of the lower lobe. He used it satisfactorily in 8 cases, with no deaths. Such contributions are of value since they point the way to greater conservation of normal pulmonary tissue in certain lesions well localized in a bronchovascular segment of the lung.

No discussion of the operative treatment of a disease is complete without reference to the risks involved. Churchill's excellent figures, as reported by Perry and King,³⁹ have been mentioned. Bradshaw and O'Neill⁴⁵ report the results of surgical treatment of bronchiectasis in 76 patients whose disorder was mostly due to an unknown etiologic agent. One death occurred among the 24 patients with disease of the lower lobe and of the lower lobe and lingula, a mortality of 4 per cent. Among 26 patients in whom one lobe was removed but disease was present in other lobes there were 4 deaths, a mortality of 15 per cent. Seventeen patients had two or more lobes removed, with 3 deaths, a mortality of 18 per cent; 11 had disease in other lobes. Maier⁴⁶ reports 64 cases in which pulmonary resections for bronchiectasis were performed. Lobectomy was done in 55 cases, and pneumonectomy in 9, with 1 operative death, a mortality of less than 2 per cent.

Bilateral lobectomy, in stages, has frequently been performed for bronchiectasis. It is now considered routinely in planning the surgical program of suitable bilateral cases. Churchill³² reports 6 cases with 1 death. We have performed bilateral excision in 4 cases with no death. As might be expected, however, and, as is borne out in Bradshaw and O'Neill's⁴⁵ figures, bilateral lobectomy is associated with considerably higher mortality, since it subjects the patient to two major operations.

Moreover, the postoperative period after the first lobectomy is rendered more hazardous because the patient must convalesce with disease remaining in one or more lobes.

PSEUDOBRONCHIECTASIS

In a communication emphasizing the importance of the effects of atypical pneumonia on the bronchi and the production of pseudobronchiectasis, Blades and Dugan⁴⁷ state that 6 patients with almost identical histories have been observed at the Walter Reed Hospital. Bronchograms, following an acute illness diagnosed as atypical pneumonia, demonstrated bronchial dilatations, but after a period of one or two months the configuration of the bronchi returned to normal. The authors therefore believe that atypical pneumonia can produce temporary enlargement of the bronchi, and urge that surgical intervention be delayed in questionable cases until repeated bronchograms and the clinical features of the disease establish an unequivocal diagnosis of anatomic bronchiectasis.

(To be concluded)

CASE 30361

PRESENTATION OF CASE

First admission. A fifty-nine-year-old mechanic was admitted to the hospital because of swelling of the legs and ankles.

The patient had been in excellent health until four months before entry, when he noticed swelling of the ankles and legs, especially at the end of the day. Soon after, he developed exertional dyspnea. He had apparently slept on two pillows all his life and continued to do so without any change. The swelling, however, increased and progressed to involve the scrotum and penis. About two months before entry he gave up his job and was hospitalized in a community hospital for one week. There he was given three pills daily and numerous injections; the nature of these was not known. The swelling of the legs subsided; he felt much better and was discharged to the care of his physician, who continued to give him two injections a week and three capsules daily. Following discharge, however, his symptoms gradually returned. He had had no orthopnea, paroxysmal nocturnal dyspnea, chest pain or palpitation. Edema of the ankles and legs and exertional dyspnea, however, progressed, and the abdomen became slightly larger. His appetite had remained essentially the same.

The past history was negative.

*On leave of absence

Physical examination showed a well-developed, well-nourished man in no discomfort. The left border of cardiac dullness was 4 cm. to the left of the midclavicular line. The rate was slow (48) but regular except for an extrasystole every tenth or fifteenth beat, with compensatory pauses. A loud systolic murmur was heard over the whole precordium but was maximal over the aortic area, accompanied by a questionable systolic thrill. The murmur was well transmitted up the neck vessels. There was a questionable early diastolic murmur to the left of the sternal border. The pulmonic second sound was greater than the aortic. Crackling rales were heard at both bases. The liver edge was palpable two fingerbreadths below the costal margin. Massive pitting peripheral edema, as well as edema of the penis, scrotum and sacrum, was present.

The blood pressure was 145 systolic, 70 diastolic. The temperature was 98.6°F., the pulse 48, and the respirations 22.

Examination of the blood showed a red-cell count of 4,100,000, with 13.4 gm. of hemoglobin. The white-cell count was 9000, with 67 per cent neutrophils. The urine gave a ++ test for albumin but was otherwise negative. A Wassermann and two Hinton tests were negative.

The patient was given 4 cc. of Cedilanid and 2.2 cc. of Mercupurin. One half hour later the radial pulse was 27, but he had no subjective symptoms. An electrocardiogram on the following day showed auricular fibrillation with an average rate of 42. The ST₁ and ST₂ waves were depressed, the T₁ and T₂ waves diphasic, and the T₃ waves low. T was inverted in CF₁. The nonprotein nitrogen was 39.5 mg. per 100 cc.

The patient was given 3 gm. (45 gr.) of ammonium chloride daily. An electrocardiogram one day after the first tracing revealed no significant change. On the fourth hospital day he was started on 0.1 gm. (1½ gr.) of digitalis daily and was given 2.2 cc. of Mercupurin intravenously which was repeated two days later. He continued to receive ammonium chloride and digitalis daily and re-

sponded well. On the tenth hospital day examination of the heart revealed slow fibrillation. The sounds were of good quality. There was no deficit. There were dry rales in the lung bases and sticky prolongation of the breath sounds. The edema had cleared except in the left calf, where it was apparently due to marked superficial and deep varicosities. The right calf was relatively unaffected. An x-ray film of the chest on the following day showed gross enlargement of the heart, both to the right and to the left. The transverse diameter of the heart was 19.5 cm., with an internal chest diameter of 34.0 cm. The lung fields were clear. There was no fluid in the costophrenic sinuses.

On the twelfth hospital day, the lungs were clear to auscultation and the patient had no orthopnea or dyspnea. There was no edema except for slight swelling of the left leg. He was discharged home on 0.1 gm. of digitalis and 3 gm. of ammonium chloride daily and a low-salt and low-fluid diet and was advised to remain inactive.

Final admission (seventeen days later). Following discharge the patient did well for one week. At the end of that period he contracted a cold, with rapid recurrence of the previous symptoms of dyspnea and edema. He then experienced increasing orthopnea. His condition progressed rapidly so that in about five days edema had reached the sacrum, involving both legs, the scrotum and the penis. Two weeks after discharge he returned to the Out Patient Department, where the intravenous injection of Mercupurin gave no relief. He was admitted two days later.

Physical examination showed an extremely dyspneic and orthopneic man with an unproductive cough. The heart was slowly fibrillating, with a rate of 60 and without any pulse deficit. The heart was otherwise the same as before. There was fluid in both lung bases, and basal moist rales. The liver edge was palpated seven fingerbreadths below the costal margin. Ascites was present as well as a marked pitting edema of the extremities up to the sacrum.

The blood pressure was 158 systolic, 88 diastolic. The temperature was 96°F., the pulse 70, and the respirations 20.

Examination of the blood showed a red-cell count of 5,020,000, with 11.5 gm. of hemoglobin. The white-cell count was 9200, with 70 per cent neutrophils.

The patient was given intravenous Mercupurin and oral digitalis and ammonium chloride. On the second hospital day he was found to be unable to void; he was catheterized, at which time only 45 cc. of urine could be obtained. This showed a ++ test for albumin, contained white cells and had a pH of 7. He was given 100 cc. of 50 per cent dextrose solution intravenously, followed by 100 cc. of physiologic saline solution, with little, if any, success. He had a great deal of respiratory

distress and became slightly cyanotic. The radial pulse rose to 90. The nonprotein nitrogen rose to 203 mg. per 100 cc. He died on the fourth hospital day.

DIFFERENTIAL DIAGNOSIS

DR. C. SIDNEY BURWELL*: I should like to begin by commenting on the electrocardiogram and by seeing the x-ray films.

DR. BENJAMIN CASTLEMAN: Would you care to see the electrocardiogram?

DR. BURWELL: The fourth lead shows a strikingly inverted T wave. There is an upward wave that I should call an R, and a deep S. The ST₁ and ST₂ waves are depressed, but only slightly so. Fibrillary waves are perfectly apparent. The rate is slow, and it appears to be quite regular. I should place it as a regular rate originating in the ventricles.

In this x-ray film the left border of the heart is not straight, but it is a rather expressionless left border. In the oblique view was the right auricle enlarged?

DR. LAURENCE L. ROBBINS: I do not believe that one can tell, but I presume that the patient was fluoroscoped and that the notation in the record was made from that. In this lateral view it is rather hard to tell whether or not the auricle is enlarged.

DR. BURWELL: It is a big lobular heart in both directions, with enlargement of most of the chambers. Certainly the left ventricle is enlarged, and I suspect that the auricles are dilated.

I find this a complex and difficult case. I should like to discuss briefly three possibilities with regard to the nature of the disease. The first decision I should like to make is whether this patient had heart failure or some other cause for this progressive and recurrent edema and dyspnea, which eventually "did him in." There are several other possibilities. First, one raises the question of whether he had obstruction of the entry of blood into the heart which was on a mechanical obstructive basis rather than because of what we call heart failure. In other words, Did he have constrictive pericarditis or pericardial effusion? I believe that the evidence is strongly against both of them. The cardiac signs did not resemble those commonly observed in either of those situations, and I am content to set that diagnosis aside.

One asks, Did he have mechanical obstruction lower down in the venous system than the right auricle? The point has been made, and with a good deal of force, that the edema started at the feet and rose to the level of the sacrum and no higher. One wonders if that is a suggestion that he had a bilateral obstruction to returning venous circulation from his legs, perhaps on the basis of recurrent thrombosis extending up into the iliac

*Research professor of clinical medicine and dean, Harvard Medical School.

system and so on, or perhaps even into the inferior vena cava. He showed no evidence of collateral circulation, which he should have if he had had obstruction to the vena cava for some time. He had a few varicose veins in one leg that seem adequately to account for the extra edema on that side, but I should hesitate to blame the edema on venous obstruction. I am always impressed by the small amount of edema that is brought about by most venous obstruction.

One then asks, Did he have cirrhosis of the liver? To ask the question is to answer it in the negative. I believe. The same can be said of nephritis.

I am reasonably satisfied to conclude that the first item in this patient's diagnoses is heart failure, and I am comforted in that conclusion by the fact that he had certain findings that ordinarily go with congestive heart failure. He had a large heart, for example, and evidence of various kinds of cardiac disease. I shall accept heart failure as the first diagnosis.

The second decision concerns the nature of his cardiac disease, and here I find the going a good deal stormier. In the first place, the evidence is not altogether conclusive. If one sees a man of this age with a large heart, which this man certainly had, with a loud systolic murmur (I think this was loud for two reasons: the record says it was, and it was heard in the vessels of the neck) accompanied by a thrill and a diastolic murmur, one can be reasonably well advised to conclude that he has aortic stenosis. Aortic stenosis is no rare disorder. It is particularly common in men of this age. It is compatible with many years of continued good health and also compatible with a short and progressive period of cardiac failure leading to death from cardiac failure. One's confidence, however, in that diagnosis is rudely shaken by the word "questionable," which is attached to the most important sign. The best evidence of aortic stenosis is an unquestioned aortic thrill. Another almost incontrovertible evidence is the demonstration of calcium in the aortic valve. I cannot see calcium, but it usually is not seen in the film. Was it seen on fluoroscopy?

DR. ROBBINS: I doubt it.

DR. BURWELL: Is there any note to that effect?

DR. CASTLEMAN: No.

DR. BURWELL: So we do not have incontrovertible evidence of calcium or the definite evidence of a thrill. My impression of aortic stenosis is further shaken by the question mark put after the diastolic murmur. It is always comforting to have an aortic diastolic murmur. Most people with loud diastolic murmurs have heart disease, and even a higher percentage of people with diastolic murmurs have heart disease. Most people with early diastolic murmurs at the left sternal border have aortic regurgitation. If a man has

aortic regurgitation he almost always has disease of the aortic valve. The diagnosis of aortic stenosis is often made on the demonstration of aortic insufficiency. This man's blood pressure is quite compatible with aortic stenosis and regurgitation. He apparently did not have a greatly elevated peripheral blood pressure, but he did have a wide pulse, which tends to support the existence of this questionable diastolic murmur. On the other hand, one cannot lean too heavily on that for several reasons. In the first place, diastolic pressures are often variable or misleading. In the second place, a person with a slow pulse rate usually has a relatively wide pulse pressure for obvious reasons; it is a long time between systoles and the diastolic pressure has that much more time to fall. So I find myself in grave uncertainty whether or not this man had an aortic regurgitation, but it does appear that he had aortic stenosis. I shall come back to that in a moment.

I think that it is unnecessary to elaborate the point that he did not have syphilitic aortitis. Most people who develop heart failure on the basis of syphilitic aortitis have free aortic regurgitation. A few people who have syphilitic involvement of the coronary orifices develop heart failure on the basis of the coronary closure, and a very few people, usually young men, develop heart failure on the basis of syphilitic myocarditis. I see no reason to inject any of these possibilities.

I do not believe that he had a congenital form of heart disease. I do not see any evidence in the auscultation or by x-ray that would permit me to judge that. No statement is made about cyanosis except that he became cyanotic in the last days of his life, so I think we can assume that he was not cyanotic before that day.

Now we come to the electrocardiogram. An alternative or possibly an addition to the diagnosis of aortic stenosis is the diagnosis of diffuse myocardial disease due to repeated coronary occlusions. I say "repeated" because there is no mention in the history of any attacks of sufficient magnitude to have given him symptoms, and because he had the small complexes and the relatively flat T waves that one often sees with rather diffuse myocardial disease. Aortic stenosis is usually accompanied by a normal sinus rhythm if it is the only valvular lesion present. When one sees a patient with aortic stenosis who has auricular fibrillation, he looks eagerly for evidence of mitral stenosis in addition. This does not appeal to me as an ideally mitral-shaped heart. There is not the slightest suggestion of even a questionable mitral murmur. There is one other point in favor of coronary disease and that is that he certainly had a high degree of auriculoventricular block. He had a complete block at the time the electrocardiogram was taken, and usually the heart rate is below 50. Coronary disease

is certainly the commonest cause of auriculoventricular block. *Digitalis* presumably accounted for a certain degree of the block.

I am inclined to conclude, on the basis of somewhat uncertain signs, that this patient had as his primary variety of heart disease an aortic stenosis. I think there is no reason to doubt that he also had a diffuse myocarditis, even though the Q wave was upright.

The third question I should like to commit myself on is the nature of the terminal anuria. I can think of three or four vascular mechanisms that give an anuria. An aortic dissecting aneurysm with compression of the renal arteries has been known to produce anuria, but there is no reason to suspect that this man had a dissecting aneurysm. The second one has certain attractions, although the thought is rather far afield, that is, a thrombosis of the *vena cava* with occlusion of the renal veins. There have been a number of cases reported. It is rare but not impossible. It is almost always accompanied either by a great deal more evidence of venous thrombosis in the legs or by obvious collateral circulation around the groins, or both. The third is an embolic occlusion of the renal arteries or a sufficiently sizable number of infarcts in both kidneys so that anuria results. It is much likelier to come about from the type of embolus that originates in the fibrillating auricle than it is from acute or subacute endocarditis. On the whole I should be inclined to think, although I find no evidence of any other embolic incidents anywhere in the body, that this anuria was due to an acute interference with renal circulation on the basis of embolism. It may be that for a brief period this patient's fibrillation ceased, to be replaced by a normal rhythm, which is one of the ideal situations for multiple embolism and may have been the thing that explains this picture. Whenever one sees a man of fifty-nine who has progressive edema without previous evidence of cardiac failure, one is reminded that there is a type of tuberculosis of the pericardium that is particularly common in old men.

Because he was a fifty-nine-year-old man who had a large heart, a very rapidly progressive affair, with no fever, no x-ray evidence and no physical signs, I shall rest the case on four diagnoses: heart failure, aortic stenosis, diffuse myocardial disease associated with coronary arterial disease, and infarction of the kidney.

DR. CHESTER M. JONES: Is it not curious that the edema was from the abdomen down, so to speak, and that he had no engorged neck veins and other signs of right-sided failure, and no left-sided failure, as evidenced by orthopnea and dyspnea, until the terminal event?

DR. BURWELL: Those are all "curious incidents" as Sherlock Holmes would have said. Some can be rationalized. As a matter of fact, exertional dyspnea was almost as early a symptom as slight swelling

of the ankles. Exertional dyspnea presumably meant that he had a slight amount of pulmonary congestion. It is possible, although I do not know and I cannot tell from the x-ray film, that he was somewhat emphysematous. There is no statement to that effect. He ended up by having orthopnea. That is one of the reasons I am inclined to think that coronary heart disease was important. I believe that the right heart must have broken down with a relatively small amount of elevation of pulmonary pressure.

A PHYSICIAN: Was there a fall in blood pressure?

DR. CASTLEMAN: It was never very high, being 155 systolic when he came in. Just before he died it was 145 systolic, 65 diastolic. It stayed about the same throughout.

CLINICAL DIAGNOSES

Arteriosclerotic heart disease, with congestive failure.

Renal failure and uremia (?cause).

DR. BURWELL'S DIAGNOSES

Congestive heart failure.

Aortic stenosis.

Myocardial disease, based on coronary-artery disease.

Infarction of kidney.

ANATOMICAL DIAGNOSES

Endocarditis, chronic, rheumatic, with moderate aortic and mitral stenosis and slight tricuspid stenosis.

Coronary sclerosis.

Myocardial fibrosis.

Acute glomerulonephritis.

Endocarditis, acute, terminal: mitral and aortic.

Pericarditis, acute and chronic.

Congestive cardiac failure.

Congestion of liver.

Ascites.

PATHOLOGICAL DISCUSSION

DR. CASTLEMAN: On the four counts that Dr. Burwell mentioned, he was correct on three. This man had heart failure. At the time of autopsy, ascites and severe chronic passive congestion of the liver were found. The heart was quite large, weighing 600 gm. He had aortic stenosis of the calcareous type, but it was mild as compared with some that we have seen. He also had a moderate degree of mitral stenosis, with thickening of the chordae tendineae, and in addition, slight involvement of the tricuspid valve; so that there is no question that he had rheumatic heart disease. There were superimposed on the mitral and aortic valves tiny

vegetations, which were merely evidence of an acute terminal endocarditis. The coronary arteries were markedly sclerotic, being narrowed in some places to pinpoint lumens. Throughout the myocardium there were small areas of fibrosis, but nothing at all recent.

The kidneys were very striking. They weighed over 600 gm., about twice the normal size, and were markedly swollen, with numerous red depressed areas scattered throughout. Microscopic examination showed old vascular disease, which accounted for the depressed areas. Every glomerular tuft was markedly swollen and filled with polymorphonuclears—findings characteristic of an acute glomerulonephritis and undoubtedly the cause of the anuria. Most of the glomeruli contained 40 to 50 polymorphonuclear cells. The tubules were swollen but contained no red cells.

DR. BURWELL: I ought to say why I ruled out tricuspid stenosis. The major reason was that he was so well up to the time he developed failure. Most people with serious tricuspid stenosis have had venous congestion of the liver for a long time. Since this patient did not have a chronically enlarged liver, I laid that diagnosis aside.

DR. CASTLEMAN: The stenosis of the mitral valve was not marked, and the tricuspid disease, although definite, was only slight. He had a pericarditis that was both old and recent.

CASE 30362

PRESENTATION OF CASE

First admission. A sixty-year-old housewife entered the hospital because of intestinal obstruction.

Twenty-two years before entry the patient had an appendectomy, and ten years later an operation for fibroids of the uterus. Since that time she had had repeated attacks of abdominal pain, tenderness and distention, relieved by medication prescribed by her family physician. For the two years preceding entry, whenever the stools were formed, they were ribbon-like; otherwise they consisted of watery fluid. On two occasions she had passed bright-red blood. Seven weeks before entry she had a severe attack of abdominal pain and was completely obstructed and distended for three days; she was relieved for three days but again became obstructed and distended for three days. At that time she first noticed a tender stationary lump in the left side of the abdomen. She had lost about 15 pounds.

Physical examination showed a well-developed pale woman with evidence of recent weight loss. The abdomen was protuberant. In the left mid-abdomen was a hard mass the size of a golf ball, which was extremely tender and slightly movable. No other organs or masses were palpable.

The blood pressure was 140 systolic, 70 diastolic. The temperature, pulse and respirations were normal.

Examination of the blood showed a red-cell count of 4,210,000, with 65 per cent hemoglobin. A white-cell count was 12,500, with 76 per cent neutrophils. The urine was normal. The stools were guaiac negative. Plain x-ray films of the abdomen showed the proximal half of the colon to be dilated and filled with feces and a small quantity of gas extending slightly to the left of the midtransverse colon.

On the third hospital day an exploratory laparotomy revealed a colloid adenocarcinoma of the splenic flexure. A Mikulicz resection was performed. The distal loop of the bowel was sutured to the lateral abdominal wall to prevent the small bowel from getting into the denuded area.

The patient did well for about twelve days, but subsequently began to have attacks of lower abdominal cramps associated with profuse bowel movements. The abdomen became distended during these attacks. In the course of the next month and a half, however, these disappeared; a clamp was then applied to the stoma, and a good spur cut through. She was discharged on the sixtieth post-operative day to return in two months for closure of the colostomy.

Second admission (three months later). After discharge the patient felt well and gained 12 to 15 pounds. The colostomy had worked well until recently, when she noticed a little bright-red blood mixed with the stools and a little bleeding from the colostomy opening.

Physical examination was essentially negative.

On the fifth hospital day the colostomy was closed. Postoperatively she was bothered by impacted feces in the rectum and, when relieved of this, developed diarrhea with abdominal cramps of the type that she had had for years. Subsequently, however, the bowel movements became normal and she was discharged on the eleventh postoperative day.

Third admission (twenty-seven months later). Following discharge the patient did well for some time but presumably had further symptoms of obstruction and was operated on in a community hospital for lysis of adhesions. She was then apparently well until ten or twelve days before re-entry, when she developed severe abdominal cramps and became distended. She was taken to the same outside hospital, where an ileostomy was performed. She developed a fecal fistula in the wound, the cramps persisted, and she was transferred to this hospital.

Physical examination showed tenderness in the abdomen, which was not greatly distended. A small rubber tube protruded from the left side at the level of the umbilicus. There was a fecal fistula to the right of and inferior to the umbilicus, with considerable porky induration about the fistula

is certainly the commonest cause of auriculoventricular block. Digitalis presumably accounted for a certain degree of the block.

I am inclined to conclude, on the basis of somewhat uncertain signs, that this patient had as his primary variety of heart disease an aortic stenosis. I think there is no reason to doubt that he also had a diffuse myocarditis, even though the Q wave was upright.

The third question I should like to commit myself on is the nature of the terminal anuria. I can think of three or four vascular mechanisms that give an anuria. An aortic dissecting aneurysm with compression of the renal arteries has been known to produce anuria, but there is no reason to suspect that this man had a dissecting aneurysm. The second one has certain attractions, although the thought is rather far afield, that is, a thrombosis of the vena cava with occlusion of the renal veins. There have been a number of cases reported. It is rare but not impossible. It is almost always accompanied either by a great deal more evidence of venous thrombosis in the legs or by obvious collateral circulation around the groins, or both. The third is an embolic occlusion of the renal arteries or a sufficiently sizable number of infarcts in both kidneys so that anuria results. It is much likelier to come about from the type of embolus that originates in the fibrillating auricle than it is from acute or subacute endocarditis. On the whole I should be inclined to think, although I find no evidence of any other embolic incidents anywhere in the body, that this anuria was due to an acute interference with renal circulation on the basis of embolism. It may be that for a brief period this patient's fibrillation ceased, to be replaced by a normal rhythm, which is one of the ideal situations for multiple embolism and may have been the thing that explains this picture. Whenever one sees a man of fifty-nine who has progressive edema without previous evidence of cardiac failure, one is reminded that there is a type of tuberculosis of the pericardium that is particularly common in old men.

Because he was a fifty-nine-year-old man who had a large heart, a very rapidly progressive affair, with no fever, no x-ray evidence and no physical signs, I shall rest the case on four diagnoses: heart failure, aortic stenosis, diffuse myocardial disease associated with coronary arterial disease, and infarction of the kidney.

DR. CHESTER M. JONES: Is it not curious that the edema was from the abdomen down, so to speak, and that he had no engorged neck veins and other signs of right-sided failure, and no left-sided failure, as evidenced by orthopnea and dyspnea, until the terminal event?

DR. BURWELL: Those are all "curious incidents" as Sherlock Holmes would have said. Some can be rationalized. As a matter of fact, exertional dyspnea was almost as early a symptom as slight swelling

of the ankles. Exertional dyspnea presumably meant that he had a slight amount of pulmonary congestion. It is possible, although I do not know and I cannot tell from the x-ray film, that he was somewhat emphysematous. There is no statement to that effect. He ended up by having orthopnea. That is one of the reasons I am inclined to think that coronary heart disease was important. I believe that the right heart must have broken down with a relatively small amount of elevation of pulmonary pressure.

A PHYSICIAN: Was there a fall in blood pressure?

DR. CASTLEMAN: It was never very high, being 155 systolic when he came in. Just before he died it was 145 systolic, 65 diastolic. It stayed about the same throughout.

CLINICAL DIAGNOSES

Arteriosclerotic heart disease, with congestive failure.

Renal failure and uremia (?cause).

DR. BURWELL'S DIAGNOSES

Congestive heart failure.

Aortic stenosis.

Myocardial disease, based on coronary-artery disease.

Infarction of kidney.

ANATOMICAL DIAGNOSES

Endocarditis, chronic, rheumatic, with moderate aortic and mitral stenosis and slight tricuspid stenosis.

Coronary sclerosis.

Myocardial fibrosis.

Acute glomerulonephritis.

Endocarditis, acute, terminal: mitral and aortic.

Pericarditis, acute and chronic.

Congestive cardiac failure.

Congestion of liver.

Ascites.

PATHOLOGICAL DISCUSSION

DR. CASTLEMAN: On the four counts that Dr. Burwell mentioned, he was correct on three. This man had heart failure. At the time of autopsy, ascites and severe chronic passive congestion of the liver were found. The heart was quite large, weighing 600 gm. He had aortic stenosis of the calcareous type, but it was mild as compared with some that we have seen. He also had a moderate degree of mitral stenosis, with thickening of the chordae tendineae, and in addition, slight involvement of the tricuspid valve; so that there is no question that he had *rheumatic heart disease*. There were superimposed on the mitral and aortic valves tiny

vegetations, which were merely evidence of an acute terminal endocarditis. The coronary arteries were markedly sclerotic, being narrowed in some places to pinpoint lumens. Throughout the myocardium there were small areas of fibrosis, but nothing at all recent.

The kidneys were very striking. They weighed over 600 gm., about twice the normal size, and were markedly swollen, with numerous red depressed areas scattered throughout. Microscopic examination showed old vascular disease, which accounted for the depressed areas. Every glomerular tuft was markedly swollen and filled with polymorphonuclears—findings characteristic of an acute glomerulonephritis and undoubtedly the cause of the anuria. Most of the glomeruli contained 40 to 50 polymorphonuclear cells. The tubules were swollen but contained no red cells.

DR. BURWELL: I ought to say why I ruled out tricuspid stenosis. The major reason was that he was so well up to the time he developed failure. Most people with serious tricuspid stenosis have had venous congestion of the liver for a long time. Since this patient did not have a chronically enlarged liver, I laid that diagnosis aside.

DR. CASTLEMAN: The stenosis of the mitral valve was not marked, and the tricuspid disease, although definite, was only slight. He had a pericarditis that was both old and recent.

CASE 30362

PRESENTATION OF CASE

First admission. A sixty-year-old housewife entered the hospital because of intestinal obstruction.

Twenty-two years before entry the patient had an appendectomy, and ten years later an operation for fibroids of the uterus. Since that time she had had repeated attacks of abdominal pain, tenderness and distention, relieved by medication prescribed by her family physician. For the two years preceding entry, whenever the stools were formed, they were ribbon-like; otherwise they consisted of watery fluid. On two occasions she had passed bright-red blood. Seven weeks before entry she had a severe attack of abdominal pain and was completely obstructed and distended for three days; she was relieved for three days but again became obstructed and distended for three days. At that time she first noticed a tender stationary lump in the left side of the abdomen. She had lost about 15 pounds.

Physical examination showed a well-developed pale woman with evidence of recent weight loss. The abdomen was protuberant. In the left mid-abdomen was a hard mass the size of a golf ball, which was extremely tender and slightly movable. No other organs or masses were palpable.

The blood pressure was 140 systolic, 70 diastolic. The temperature, pulse and respirations were normal.

Examination of the blood showed a red-cell count of 4,210,000, with 65 per cent hemoglobin. A white-cell count was 12,500, with 76 per cent neutrophils. The urine was normal. The stools were guaiac negative. Plain x-ray films of the abdomen showed the proximal half of the colon to be dilated and filled with feces and a small quantity of gas extending slightly to the left of the midtransverse colon.

On the third hospital day an exploratory laparotomy revealed a colloid adenocarcinoma of the splenic flexure. A Mikulicz resection was performed. The distal loop of the bowel was sutured to the lateral abdominal wall to prevent the small bowel from getting into the denuded area.

The patient did well for about twelve days, but subsequently began to have attacks of lower abdominal cramps associated with profuse bowel movements. The abdomen became distended during these attacks. In the course of the next month and a half, however, these disappeared; a clamp was then applied to the stoma, and a good spur cut through. She was discharged on the sixtieth post-operative day to return in two months for closure of the colostomy.

Second admission (three months later). After discharge the patient felt well and gained 12 to 15 pounds. The colostomy had worked well until recently, when she noticed a little bright-red blood mixed with the stools and a little bleeding from the colostomy opening.

Physical examination was essentially negative.

On the fifth hospital day the colostomy was closed. Postoperatively she was bothered by impacted feces in the rectum and, when relieved of this, developed diarrhea with abdominal cramps of the type that she had had for years. Subsequently, however, the bowel movements became normal and she was discharged on the eleventh postoperative day.

Third admission (twenty-seven months later). Following discharge the patient did well for some time but presumably had further symptoms of obstruction and was operated on in a community hospital for lysis of adhesions. She was then apparently well until ten or twelve days before re-entry, when she developed severe abdominal cramps and became distended. She was taken to the same outside hospital, where an ileostomy was performed. She developed a fecal fistula in the wound, the cramps persisted, and she was transferred to this hospital.

Physical examination showed tenderness in the abdomen, which was not greatly distended. A small rubber tube protruded from the left side at the level of the umbilicus. There was a fecal fistula to the right of and inferior to the umbilicus, with considerable porky induration about the fistula

and over the central part of the abdomen, associated with cramps. When the abdomen tightened, it bulged, peristalsis increased, and then gas and feces extruded.

Examination of the blood showed a white-cell count of 10,400, with 75 per cent neutrophils. The serum chloride was 87 milliequiv. per liter, and the protein 5.1 gm. per 100 cc.

The patient was given a transfusion, and an enterostomy was performed. Postoperatively there was some relief, but she continued to have attacks of abdominal cramps. On the sixteenth day she had a spontaneous bowel movement by rectum. She gradually improved. The enterostomy tube was clamped and taken out. Drainage stopped, and she was discharged on the forty-third hospital day.

Fourth admission (six years later). Following discharge the patient did well until one year before re-entry, when she noted that the stools were covered with blood. Ten days before admission she became obstructed, with marked distention. Four days later she had a bout of severe abdominal pain, followed two days later by the passage of small amounts of blood with the stools on three or four occasions. Two days before entry she had a massive hemorrhage and apparently went into shock, since she awoke lying on the bathroom floor without any recollection of falling, but with bruises on the face and head. She was brought into the hospital shortly thereafter. No additional information was available.

Physical examination showed a pale, thin woman in no distress. There was considerable evidence of weight loss. The heart and lungs were normal. A small sausage-shaped nontender mass was palpable immediately above the umbilicus.

The blood pressure was 140 systolic, 90 diastolic. The temperature, pulse and respirations were normal.

Examination of the blood showed a hemoglobin of 9.1 gm., and a white-cell count of 7400, with 82 per cent neutrophils. The urine showed a + test for albumin. The stools were tarry and liquid, with a +++ guaiac test. The nonprotein nitrogen was 25 mg. per 100 cc., and the serum protein 5.8 gm. Barium examination of the colon showed an area of narrowing toward the lower end of the descending colon, which fluoroscopically was thought to be due to spasm but on the films was suggestive of an annular filling defect. No obstruction to the free flow of barium was encountered. In the midtransverse colon was an annular defect measuring 8 cm. in length, with an irregular lumen and shelf formation at either end. This defect was constant and coincided with the sausage-shaped mass in the abdomen. The right colon filled normally. A postevacuation film showed complete contraction of the colon and that most of the barium had been expelled; the filling defect in the transverse colon showed no change in its configura-

tion, and the appearance of the narrowing at the lower end of the descending colon was less conclusive.

The patient was given several transfusions, and on the seventeenth hospital day an operation was performed.

DIFFERENTIAL DIAGNOSIS

DR. IRA T. NATHANSON: The findings in this patient at the time of the last admission are those of a lesion of the colon. Questions arise whether the lesion was benign or malignant and whether it was related to the previous illness.

One may first consider the possibilities of a benign lesion. Chronic granulomas, such as tuberculosis and syphilis, may occur in the colon. Tuberculosis may exist in the colon as a localized process either in the hyperplastic or ulcerative form. In a fairly high percentage of cases, however, it is an accompaniment of the disease elsewhere and is usually confined to the cecum and ascending colon. The localized type of disease may produce obstruction and involve the bowel in an annular fashion when deep ulceration occurs. A mass may sometimes be palpated, but massive bleeding is rare, although it may occur in the ulcerative type. The apparent absence of extracolonic tuberculosis, the location of the lesion, the massive bleeding and the past history seem to rule out tuberculosis. Syphilis is certainly a rare entity especially without other evidence and, like sarcoid, which is said to occur in the large bowel, can be dismissed.

Chronic diverticulitis is a remote possibility. In general, the process is diffuse, and in well over half the cases it involves the sigmoid. When other parts of the colon are affected it is unusual not to have coincident lesions in the sigmoid. The symptoms prior to and soon after the resection of the splenic flexure may have been caused by diverticulitis, since carcinoma and diverticulitis may co-exist. I should, however, expect better x-ray evidence, as well as other signs and symptoms between the third and fourth admissions. Finally, bleeding is a relatively rare symptom in diverticulitis.

Segmental ulcerative colitis may also be mentioned. As a rule it appears in young people, the symptoms are profound, and it almost always involves the rectum and sigmoid colon. X-ray examination usually reveals characteristic signs, particularly evidence of inflammation of the mucosa, in addition to a defect. Furthermore, proctoscopic examination usually yields significant information.

Of the benign tumors, which include many varieties, adenomas or polyps deserve the only consideration. These are frequently multiple and occur with greatest frequency in the left half of the colon, particularly the lower portion. Occasionally, they are of sufficient size to produce obstructive symptoms and may ulcerate and bleed. They seldom

become large enough to be palpated on abdominal examination and are rarely, if ever, capable of producing the picture of an annular defect by x-ray examination. Intussusception, which is usually due to a polyp that has ulcerated and bled, may mimic the present picture; however, shelf formation, as seen by x-ray examination, is apparent at only one end.

Finally, we arrive at the most likely diagnosis. The symptoms, physical signs, laboratory evidence and x-ray findings are compatible with a malignant neoplasm of the colon. The decision must be made whether this was a carcinoma or one of the rarer lesions, such as a malignant lymphoma, a malignant carcinoid or even a malignant melanoma. Malignant lymphoma arises most frequently in the region of the cecum and from the submucosal lymphoid tissue of the bowel wall. It follows the cleavage planes and therefore may grow to a considerable size before obstruction, annular constriction and ulceration with hemorrhage appear. The other lesions are only of academic interest.

It therefore seems apparent that the syndrome was produced by carcinoma. Two questions arise that must be answered. Was this a new or recurrent tumor? Was it a single or a double lesion? The disease may have represented an extension of the previous carcinoma of the splenic flexure. Processes were described in the midtransverse colon and in the lower end of the descending colon. Each of these is a considerable distance from the first carcinoma, and from the x-ray report one may assume an area of normal bowel in the region of the bowel resection, which was between the two lesions described. Moreover, it is very unusual to find a recurrence of a cancer of the colon after a five-year interval of freedom from disease. According to the history, the final symptoms appeared about seven and a half years after the first admission. Hence, there seems to be little doubt that the original lesion was cured. It is well recognized that multiple primary cancers of the colon may occur simultaneously or successively over a period of years. When two or more cancers occur simultaneously they frequently arise in pre-existing polyps. Successive malignant changes in polyps, however, are also possible. In this case such a situation may have occurred. Thus it is problematical whether this was a single or a double lesion and whether the origin was in a polyp. The absence of polyps by x-ray examination, even though they are occasionally difficult to demonstrate, and the variability of the findings in the descending colon suggest a single primary cancer of the transverse colon. Such a lesion can arise in a polyp, and if one accepts the presence of a second cancer in the descending colon, then origin from a polyp is likely.

The x-ray defect in the lower colon seems to have been due to spasm, which often occurs, especially after a bowel resection.

If one ventures a guess concerning the type of such a neoplasm, it should be based on the location of the lesion, the form most frequently seen at that site, and the history. Cancer of the transverse colon is usually of the scirrhus type, which produces annular constriction of the colon. It may remain localized for a relatively long period of time and thus may attain considerable size before producing severe symptoms. The type of lesion seen oftenest is an adenocarcinoma, particularly if it arises on the basis of a polyp. In general they are of low to moderate malignancy.

CLINICAL DIAGNOSIS

Carcinoma of transverse colon.

DR. NATHANSON'S DIAGNOSIS

Primary adenocarcinoma of transverse colon (moderate malignancy).

ANATOMICAL DIAGNOSIS

Primary adenocarcinoma (Grade II) of transverse colon.

PATHOLOGICAL DISCUSSION

DR. BENJAMIN CASTLEMAN: As Dr. Nathanson has indicated, once having decided that the lesion in the transverse colon was a carcinoma, it is interesting to speculate whether the lesion was a recurrence or a new tumor. The resected specimen of transverse colon, which was 34 cm. long, contained a large annular ulcerated carcinoma 8 cm. in length. The site of the previous well-healed enteroenterostomy was 17 cm. away from the tumor, so that I believe there can be no question that the carcinoma was a new one rather than a recurrence. It was of a moderate degree of malignancy.

Because of the numerous previous abdominal operations, the peritoneal cavity was completely obliterated by adhesions, except for a small area in the right upper quadrant, and the surgeon had a difficult time isolating the proximal transverse colon for resection in order to make sure of the blood supply of the distal portion. Finally, an end-to-side anastomosis between the ascending colon and the sigmoid was performed. No lesion was observed in the descending colon.

The patient left the hospital on the twenty-third postoperative day. Since the regional lymph nodes were not involved, the prognosis should be good.

MASSACHUSETTS EMIC PROGRAM

WORRY is a dangerous liability to men in combat, and release from the financial exigencies of impending parenthood is one benefit of the Emergency Maternity and Infant Care Program the importance of which cannot be minimized from either the medical or the military viewpoint. More than 1900 Massachusetts physicians have signified their willingness to provide medical care for the 12,184 cases already authorized by the program, which means, as stated elsewhere in this issue of the *Journal*, that more than 10,000 servicemen serving at home and abroad are fighting the war with the assurance of complete, competent medical care

for their wives — not only during pregnancy but also for any acute condition beginning in the first six weeks post partum — and for their infants, including care during sickness and immunization against smallpox, diphtheria and whooping cough. Similarly, the vast majority of Massachusetts hospitals are participating in this wartime service. That all this is greatly appreciated is evidenced by the many letters from servicemen received by the Massachusetts Department of Public Health, which, incidentally, deserves unstinted praise for the way in which the program has been organized and administered in the Commonwealth.

The EMIC program was created to relieve servicemen of the four lowest pay grades of the burden of debt through furnishing this specific type of medical care for their wives and infants, and is not intended to benefit any other group. The rules and regulations were promulgated by the Children's Bureau of the United States Department of Labor, and the states merely act as administrative agencies. The latter are not permitted a great deal of latitude in interpretation except to modify, subject to the approval of the Children's Bureau, regulations that conflict with state laws and practices. All fee schedules used in this program are within the permissive limits set by the Children's Bureau and are subject to the latter's approval.

The original program was planned for the general practitioner, but liberalization of its activities now calls for the services of specialists as qualified consultants. Of course, if a specialist is willing, he may care for a patient as an attending physician.

The EMIC program as a whole and certain of its rules and regulations have been severely criticized and even rejected by several national and state medical societies largely because it is believed that the program is an entering wedge for "state medicine." It should be borne in mind, however, that, in addition to contributing to the morale of the armed forces, the program is an emergency procedure, that, according to the Children's Bureau, it will terminate six months after the war is ended and that, in many sections of the country, it has provided maternal and infant care that would otherwise have been either inadequate or unavailable. The enthusiastic response of the physicians

of Massachusetts attests to their willingness further to assist in the war effort, even though many of them do not approve of certain of the principles involved in this type of medical care. Furthermore, the outcome of the program may provide a means of determining whether this is the type of medical care that the people of the United States want as a steady diet.

"COLD VACCINES"

EACH year as the summer comes to a close and the season for colds begins, persons who regularly suffer from frequent colds and their sequelae seek relief from a recurrence of their difficulties. This is especially true among persons who have had a particularly bad time with colds during the preceding year. Because of the large number of persons afflicted each year, almost every physician is confronted with such cases and has to cope with this problem. Moreover, many physicians are victims of frequent colds, which they are desirous of preventing.

The great majority of physicians frankly admit that they do not know of any method of preventing or reducing the incidence of colds, except perhaps by general hygienic measures, which are thought to "increase resistance" and perhaps also by limiting exposure through contact with persons already manifesting the symptoms of a cold. Neither of these methods can be expected to yield startling beneficial results. Many physicians, on the other hand, state that, although they have no specific means of preventing the colds, the etiologic agent of which is presumably a virus, they are hopeful of preventing the sequelae of colds, which are usually caused by the common bacterial pathogens of the respiratory tract. They therefore resort to vaccines prepared against the more frequent bacteria, namely, pneumococci, streptococci, staphylococci, influenza bacilli and, perhaps, Friedländer bacilli. They hope thus to immunize the sufferers in some specific or perhaps nonspecific way against secondary infections with these organisms.

It is now well known that most of these respiratory pathogens are represented by numerous specific types and that immunity is for the most part type-

specific in character. In other words, it seems futile to attempt immunization against all or even any one group of these organisms. Yet these bacterial vaccines, which are obligingly prepared even by reputable pharmaceutical firms in response to the demand, are regularly given by many physicians in a "shotgun" manner. Carefully controlled clinical experiments on the prevention of colds are difficult to carry out. When they have been done, it is only rarely that any beneficial results from these vaccines have been noted.

In wartime, since colds constitute the major cause of absenteeism from work, their prevention becomes an acute problem. One of the recent attempts to conduct a controlled experiment with commercial cold vaccines has been reported by McGee and his associates* in the Medical Department of the Hercules Powder Company. These industrial physicians used three oral and two parenteral vaccines that are currently offered by commercial laboratories for prophylaxis against the common cold. Their study was carried out in a group of over 1000 industrial and office workers during the October-to-April seasons of 1941 and 1942 and of 1942 and 1943. Placebos were given to some of the subjects, who thus served as controls. Their results are worth quoting:

An examination of the average number of colds suffered per person, the number of days lost per person because of these infections and the number of days lost per infection suggests no outstanding value for any vaccine included in this clinical test. By assigning possible significance to slight differences to the arithmetical averages of the various categories shown in the table, one notes the following: the fewest colds developed in groups receiving either Vacagen, Sharp and Dohme vaccine for parenteral use or a placebo by mouth; groups receiving Oravax, a placebo (orally or hypodermically) or taking no prophylactic medication at all lost fewest days from work because of colds; groups receiving a placebo hypodermically, Oravax or nothing at all have the mildest infections (measured by the length of absence per acute cold reported).

In view of the behavior of the control groups, we find no evidence of clearly effective prophylaxis against either the frequency or the severity (including complications) of the common cold from the use of any of the vaccines studied.

From these studies, McGee and his co-workers conclude, "No clearly evident protection against

*McGee, L. C., Andes, J. E., Plume, C. A., and Hinton, S. H. "Cold vaccines" and incidence of common cold. *J. A. M. A.* 124:555-557, 1944.

the cold and related acute respiratory infections can be demonstrated in the results of this clinical trial at mass immunization." They are therefore led to the further conclusion, "The indiscriminate use of cold vaccines which are now available is not the answer to the problem of industrial absenteeism due to acute respiratory infections." Once again, it has been shown that the administration of "cold vaccines" merely means a waste of the physician's time and of the patient's money.

MASSACHUSETTS MEDICAL SOCIETY COMMITTEE ON PUBLICATIONS

The *Journal* lacks extra copies of the January 13, May 11 and June 1, 1944, issues. Many requests have been made by libraries and other subscribers who wish to bind Volume 230 but who did not receive those particular issues, owing to the difficulties accompanying a change of printers. If any subscribers who do not bind their copies have the January 13, May 11 and June 1 issues on hand, the *Journal* will gladly pay 15 cents for each copy left at or mailed to its office (8 Fenway, Boston 15).

RICHARD M. SMITH, *Chairman*

MASSACHUSETTS DEPARTMENT OF PUBLIC HEALTH

EMERGENCY MATERNITY AND INFANT CARE PROGRAM

More than 10,000 prospective mothers have been accepted for care under the Emergency Maternity and Infant Care Program since it went into effect in Massachusetts last September. The total expenditure for the care of these cases will exceed \$1,500,000, which will be allotted to physicians and hospitals. That this program has proved a boon to the thousands of wives and babies of Massachusetts servicemen in the fourth, fifth, sixth and seventh pay grades is quickly recognized.

Effective August 1, additional physician's services were made available to the wives and infants accepted for care under this program. Each physician will be sent a statement through the mail about the program, and a complete description is available either in the library or in the superintendent's office of each participating hospital. The changes are as follows:

Maternity Care

Medical. The attending physician may receive payment for the treatment of conditions not attributable to pregnancy, both in the home or in the hospital during pregnancy and the post-partum period. Office treatment of intercurrent nonobstetric conditions is included in the overall fee for maternity care.

Surgical. The attending physician may receive payment for surgical conditions not attributable to pregnancy (such

as appendicitis) during the maternity period, which includes a six-week post-partum period, provided that he qualifies as a consultant in a surgical specialty. If the attending physician does not qualify as a consultant in a surgical specialty, he may call a consultant, who will receive payment for any operation he may perform. (There has been no change in the ruling that the attending physician — even though qualified as a consultant — must call another consultant for an obstetric operation if an additional charge for the operation is to be made. No extra fee may be granted to the attending physician for an obstetric operation.)

Continuing care. If a serious acute condition beginning before the end of the six-week post-partum period continues uninterruptedly beyond that period (as in phlebitis), the attending physician may be paid for home or hospital care of this condition continuing beyond the six-week post-partum period. Hospitalization at ward cost, bedside nursing and consultant service may also be paid for under these funds.

Note: All services for which payment is expected must be requested at the beginning of the illness. This request may be made by the physician or hospital by letter or by telephone (CAPitol 4600).

These new services are not retroactive, and payment will not be made for conditions occurring prior to August 1, 1944. Bills for professional services should be sent only after authorization has been received.

Infant Care

Immunizations. Immunizations for smallpox, diphtheria and whooping cough are now included in the program. A maximum payment of \$6.00 for this service will be made to the private physician if no other immunization facilities are locally available. Where immunization facilities are available at local health-department clinics, no payment may be made. If given at pediatric clinics or well-child conferences, the usual clinic fee may be paid, not to exceed the maximum per visit of 50 cents.

Biologicals. Whooping cough, smallpox, diphtheria and combined whooping cough and diphtheria biologicals are furnished free for infants authorized under this program. An addressed postcard requesting biologicals will be attached to the authorization, and this should be mailed directly to the Antitoxin and Vaccine Laboratory by the attending physician.

Crippling conditions. Infants with crippling conditions will be transferred to Services for Crippled Children.

Circumcision. A fee for circumcision is not included under this program.

Consultant Service

Services of a consultant are available provided he meets the standards described in the July 6 issue of the *Journal*, and such services are authorized.

Assistant Service

If no member of the resident hospital staff is available, a private physician may be paid for assisting at a major operation.

BOOK REVIEW

Walter Reed: Doctor in uniform. By L. N. Wood. 8°, cloth, 277 pp., with 18 illustrations. New York: Julian Messner, Incorporated, 1943. \$2.50.

The life of Walter Reed, one of the pioneers in bacteriology in this country, whose fame rests largely on his experiments in Havana, carried out on human beings, which show that the common house mosquito was responsible for the spread of yellow fever, is well known to all members of the medical profession. Mrs. Wood has taken this fascinating story and written it in a simple, straightforward manner, particularly aimed at a popularization of Reed's life for children.

The book is exceptionally well written and should have a wide appeal, for the author is particularly skillful in drawing a picture of an outstanding man in American medicine. The account is accurate, and there is an excellent bibliography, as well as an adequate index. The illustrations are particularly good, and the whole book gives a splendid picture of the man and his accomplishments. It may be highly recommended.

PSYCHIATRIC CASUALTIES OF WAR AND THEIR TREATMENT*

WINFRED OVERHOLSER, M.D.†

WASHINGTON, D. C.

IT IS no exaggeration to say that in the present war the most important medical problem is that of the treatment and prevention of psychiatric casualties. Certainly those who are familiar with the experience of World War I will not be astonished by such a statement. To date the United States Government has spent well over \$1,000,000,000 for the compensation and hospitalization of the nervous and mental casualties of World War I, and even now about 67,000 veterans of that war are receiving compensation for psychiatric disabilities that have been adjudicated as due to service. As a result of the legislative provision that veterans of 1917 and 1918 are eligible for care whether or not their disability is due to service, the psychiatric hospital peak load for World War I has not yet been reached. Whether the rate of incidence of neurologic and psychiatric disorders is greater in this war than it was twenty-five years ago is at the moment uncertain. It may, however, be safely said that on account of the vastly greater size of the armed forces, the number of cases developing must be large. Certain figures published in the January 14, 1944, issue of the *Congressional Record* indicate that out of a total of 3,437,000 registrants rejected from the draft, those rejected for mental disorders constituted 14.5 per cent, those for neurologic disorders 5.4 per cent and those on the ground of mental deficiency 3.3 per cent.

From the experience of World War I it was the hope and expectation that a careful selection of registrants at the induction level would bring about a lowering of the discharge rate for nervous and mental disorder. Unfortunately, that expectation has not been fulfilled. According to the same issue of the *Congressional Record*, the Selective Service System reported that up to January 1, 1944, of the discharges from the Army, 44.6 per cent have been for neurologic and psychiatric conditions. Of these, psychoneurosis led, with 32 per cent of the

discharges. Indeed, the next most frequent cause, schizophrenia — or, as it is sometimes still referred to, dementia praecox — constituted only 4.1 per cent of the total. Epilepsy and neurologic disorders accounted for 2.2 per cent each, and other psychiatric conditions were even less numerous.

The person who leaves civilian life to enter the Army finds himself faced by a number of psychological hazards.¹ One of the greatest of these is the loss of individuality, but there are others. The strict regimentation, the loss of initiative and privacy, the sudden deprivation of dependency on home and family, the sense of loneliness and homesickness, are all factors that are prominent in studies of the psychiatric casualties. The alteration in attitudes toward human life calls for a radical readjustment and reassessment of values. To all these hazards are added, particularly under combat conditions, various physiologic insults caused by mud, vermin, various diseases and loss of sleep and, above all, by sustained fear. Under these added stresses it is perhaps strange that more men do not develop a condition in which their psychological equilibrium can no longer be maintained. On the compensating side it should be pointed out that there are certain constructive phases of military life. The soldier has excitement and change, and he is freed of many of his civilian problems and of the various frustrations of civilian life. If he feels confidence in his leaders and in the cohesiveness of his organization, his own feelings of security and power are increased. It is this mechanism that operates so powerfully under the name of "morale" — perhaps the most important single factor in the rate of incidence of neurosis. There is an identification with the interests of the country in duty and service, and new authority is gained, together with greater maturity. Some neurotic persons, particularly those of an obsessive compulsive type, may fit in particularly well to this picture. Certainly one can say that even though the balance in war is always on the debit side, there are constructive factors, and obviously the majority of men make a

*Presented at the annual meeting of the Massachusetts Medical Society, Boston, May 23, 1944.

†Professor of psychiatry, George Washington University School of Medicine, and superintendent, St. Elizabeths Hospital, Washington, D. C.

working adjustment to the stresses that they meet in military life, just as they do to those encountered in civilian life.

Although the psychologic factors involved in the military situation are of a special nature, the reactions to them follow general patterns that are familiar to psychiatrists in civilian practice. Human nature, in short, does not change either in its aims or in its manners of defense. As a general thing it may be said that the psychiatric reactions of war tend to be somewhat more superficial, to run a shorter course and to be more readily amenable to treatment, particularly removal from the specific situation, than is the case with similar types of reaction occurring among civilians.

The psychotic reactions — that is, those reactions that in civilian life would ordinarily call for commitment to a mental hospital — may be dismissed in a comparatively short space. Probably the most frequent psychotic reaction is what is generally diagnosed as acute catatonic excitement or, as Kempf would term it, acute homosexual panic. This condition arises not infrequently in the early days of camp life and is characterized by a sudden onset with marked overactivity, fearfulness, confusion and active auditory hallucinations in which the voices accuse the patient of homosexual practices or inclinations. There may be assaultiveness, and there is frequently refusal of food, which, in connection with the overactivity, may bring about an early dehydration, exhaustion and occasionally even death. It seems likely that many of these reactions are precipitated in latent homosexuals who suddenly find themselves in the midst of large numbers of others of their own sex with little or no privacy. This type of reaction is far from unknown in civilian life, and the recovery rate in state hospitals is not insubstantial. The response to hospital care, particularly with prolonged sedation and interviews with the patient under the influence of Sodium Amytal, is substantially higher and the course, although stormy, is usually brief.² Among the other psychoses are found more rarely depressions, and somewhat more frequently mild manic episodes. These, too, are usually readily responsive to treatment.

Among the psychiatric casualties of war, the psychoses pale into insignificance as compared with the psychoneuroses. In connection with the neuroses an observation may be made about what may be termed "the styles." Just as the *grande hystérie* of Charcot had become practically obsolete by the time of World War I, so it is now found that the trend in the neuroses — at least in the military sphere, and probably in the civilian as well — is away from the conversion hysterias, which were frequent in 1918, in favor of the anxiety states. Anxiety neurosis clearly leads the list among the neuroses. In this condition there is a prevailing mood of worry, with acute attacks of free-floating or un-

fixated anxiety, accompanied by the autonomic symptoms of flushing, sweating, tremors, palpitation and dyspnea, the startle reaction and disturbances of sleep, often accompanied by terrifying dreams. This condition, although not confined to the combat areas, is generally attributed to some catastrophic event, such as an explosion near by, a torpedoing or the death by violence of a comrade. It should always be borne in mind that any person may, if the stress is sufficiently prolonged and sufficiently severe, develop a state of this sort. No one is immune to the neuroses. Often the fundamental conflicts are found not to be the fear of immediate dissolution, but rather to concern domestic situations or other civilian problems, some of which have evidently been in existence for a long period. In general it may be said, just as was found in the follow-up of a group of psychoneurotic patients after World War I, that the more clearly exogenous are the precipitating factors, the better are the prospects. It was found, for example, in 1918 that those victims of neurosis who went back to duty in the largest proportion were those who had been exposed to the concussion of high explosives; their conditions were diagnosed, for example, as concussion syndrome, traumatic syndrome and exhaustion neurosis. A far smaller proportion of those with hysteria were returned to duty than was the case with those with relatively mild and superficial anxiety states that developed following a clear-cut precipitating episode.

Conversion hysteria, which was one of the ordinary conditions in 1917–1918, is relatively less frequent today, although not by any means unknown. A number of conditions, somewhat allied, are grouped under the current heading of "psychosomatic disorders." Effort syndrome, in which one found attacks of dyspnea, sweating, tremulousness and precordial pain, was described by Da Costa soon after the Civil War under the title of "soldier's heart," and was recognized even then as presumably functional in origin. It was frequent in World War I, but is probably somewhat less so in the present conflict. It is generally recognized that a considerable group of gastrointestinal disorders are likewise essentially emotional in origin. This group is not larger entirely on account of the increased diagnostic acumen of the internists, although with the increasing stress now being laid on the importance of psychosomatic medicine this is a factor that cannot be disregarded.

The list of disorders that have been discussed is far from exhaustive, but it represents the principal types of psychiatric casualty likely to be encountered in the military experience. The degree of severity of the symptoms varies, as do some of the specific situations in which certain of the symptoms develop. One thinks, for example, of some of the special problems of aviation medicine, of tank warfare and of fighting in the jungles. The mechanisms, as may

properly be repeated, are fundamentally the same, though the precipitating conditions are different. It is extremely doubtful whether any useful purpose is served by coining new names for these conditions. One hears much nowadays of combat fatigue, fatigue syndrome, flying stress, operational stress and so on, just as one heard of shell shock in World War I.³ These attempts to establish new terminology apparently stem from the idea that there is something inherently disgraceful or improper about the development of a psychoneurosis. If the same amount of energy were put into educating the military and the public concerning the true nature of neurosis as is now devoted to the coining of new names, we should probably be making far more progress!

In a recent issue of a widely read magazine that has never been particularly noted for the accuracy of its medical articles, the readers were informed that there was no curative treatment of psychiatric casualties in World War I, that very few of the men recovered, and that as a result the psychiatric hospitals of the Veterans Administration are now crowded with this "débris of war," whereas a curative treatment has now been developed that is redeeming casualties for combat or useful noncombat duties. The remarks concerning World War I are an interesting example of the manner in which Americans characteristically forget the past. Documentary evidence is readily available that a great deal was done in 1917-1918 in the line of the early treatment of neuroses near the front lines, and it is likewise clear that a very substantial number of men were sent back within ten days or less to front-line duty.⁴ During the Meuse-Argonne drive, for example, 75 per cent of the men treated for war neuroses at the field hospital were returned to duty in an average of four days, and only about 4 per cent of recurrences were found. Rest, occupation and psychotherapy, the very things that are being stressed today, one finds emphasized then. This is not to say, however, that no progress has been made in the line of therapy. Much, indeed, of a constructive nature has taken place.

Much has been learned since World War I of the psychologic mechanisms of these casualties, and there have been learned, too, several new approaches to the patient that enable psychotherapy to be more effective. Among the newer methods perhaps the most significant is what has been variously termed "narcoanalysis" and "narcosynthesis" or "Amytal interviews." The first term was invented by Horsley⁵ in 1936, and the second has been utilized more recently by Grinker⁷ in describing his significant work in the North African campaign. The treatment consists in the intravenous administration of Sodium Amytal or Pentothal Sodium in a dose sufficient to bring about a moderate degree of narcosis (5 to 7½ gr.). This treatment is a valuable aid in releasing inhibitions, overcoming the

resistance of the patient and enhancing his suggestibility. It may be utilized in the treatment of the neuroses and even of the psychoses, particularly when the patient is inaccessible. It provides an access to the deeper layers of consciousness, and not infrequently a patient talks freely who without the drug would be completely mute. In the stage of suggestibility brought about immediately after the administration of the drug, hysterical symptoms may be caused to disappear, and it can then be demonstrated to the patient that his disability is not a permanent one. Narcoanalysis is a valuable procedure that is being widely used with great success. It requires no apparatus except the hypodermic syringe, can be utilized at points near the front lines and has been used in a large number of cases in restoring soldiers to active duty. It should always be remembered, however, that the drug constitutes merely a useful adjuvant to psychotherapy. The important feature of this method of treatment is the increased accessibility of the patient to the ministrations of the therapist; to this extent, it really should hardly be classified among the drug therapies.

Continuous narcosis treatment calls for hospital facilities and a good deal of nursing attention. It has not been so promising as was hoped when it was first introduced, and it is likely that the simpler method of narcoanalysis provided all the benefits, except that in cases of profound exhaustion the continued narcosis provides a long period of much needed rest.

A few words should be said about the various types of what Strecker⁸ has aptly termed "the drastic therapies." Insulin-shock therapy is not especially applicable in these cases, although Sargant⁹ has used what he terms "sub-shock insulin therapy" and has found it useful as a general tonic in cases of war neuroses, and also as a sedative therapy in excited states. The Metrazol treatment of Meduna has been found to have certain disadvantages and has been almost entirely replaced by the electric-shock treatment of Cerletti. The latter has been particularly useful in the treatment of the depressions, and is therefore applicable largely in general or station hospitals rather than nearer the front lines. In the depressions there is always danger of suicide, hence any treatment that shortens the course of the disorder not only benefits the patient but results in a saving of available man power among the hospital personnel. The electric-shock method is not without risk, however, and should not be employed without the precaution of a thorough physical examination, in addition to x-ray examination of the chest and spine, and preferably (at least in patients past thirty) an electrocardiogram. Obviously physiologic changes take place when the electric current is passed through the brain of the subject. I find it hard, however, to agree with Myerson¹⁰ who has stated

categorically that the value of shock treatment does not appear to have a psychologic foundation. He proceeds to say, rather, "Physiologic alterations of an unknown type take place and this is the basis of the recovery." To many of us one of the values of the shock treatments in general and of electric-shock in particular has seemed to be that it placed the patient in an especially dependent situation with relation to the physician, and that in turn it directed the physician's attention to the needs of the patient, thus bringing about a closer rapport. Indeed, electric-shock or other shock therapy, without psychotherapy, — that is, the impact of the personality of the physician on the patient, — is likely to fail of its full effect. There is no royal road, even an electrical one, to the cure of mental disorders, but there is no doubt that electric-shock therapy has been of great value, particularly in the treatment of the depressions. It has likewise been found useful in acute maniacal conditions.

Years ago Pratt¹¹ demonstrated effectively what could be done in the line of group therapy. The work that he started is being confirmed and developed in many different ways today. Psychotherapy is a time-consuming process. The number of persons who need it is large, and the floating supply of psychiatrists is small. Two things must be done if adequate treatment is to be given to the patients being considered. One is to develop in nonpsychiatrists an appreciation of the importance of emotional conflict and the need and the value of psychotherapy. The other is to arrange for the treatment of groups of patients, thus multiplying for practical purposes the amount of time that the therapist may employ per patient. Group discussions are being used at various centers with substantial success, and at a few points a specialized form, the psychodrama, has proved successful.

Among other forms of therapy one certainly must not fail to mention occupational therapy, a form that was utilized overseas during World War I, and which is again being developed by the Army. It seems probable that its value will eventually be fully recognized again, as it was in 1918. Various physiotherapeutic approaches, some of which have already been mentioned, are of value, partly on account of the physiologic changes brought about by them, and partly on account of the psychologic factors involved.

Time does not permit a more detailed consideration of a long and complicated subject. Enough has been said, however, to indicate that although the incidence of psychiatric casualties is substantial,

the prognosis, both for the psychoses and for the neurotic manifestations, is better than one would expect to find with similar symptoms in civilian life.

What of the future? One of the greatest defects of public education at the moment is shown in the lack of the proper attitude toward the psychiatric dischargee and rejectee. The attitude of the family, the attitude of the employer and the attitude of society as a whole leave much to be desired. Too many persons fear the man who is known to have suffered a psychiatric disability in service. They fear that he is a "raving maniac," that he is unsafe to have about, that he is so changed a person that he should be looked on as a pariah. There are employers who refuse to re-employ a man known to have been discharged for a psychiatric cause. Such a situation is tragic and must be rectified if the improvement of these men is to be maintained. If the dischargee comes home to find himself rejected, he loses confidence and may readily suffer a relapse. One may question also what the effect of the generous compensation laws enacted by Congress is to be. It may well be that cases will be kept active because recovery is to be penalized by loss of a fixed income. In this regard war casualties of a psychiatric nature are likely to be similar to unsettled industrial-compensation cases. If lump-sum settlements could be arranged, it is likely that greater inducement would result for the recovery of the patient. Finally and most important, if these men on returning can be made to feel that they are respected, that they are wanted, that their place in the community is secure and that work is available for them, we may safely dismiss any fears that we are to be overwhelmed by a flood of permanent psychiatric casualties of war.

POTASSIUM BICARBONATE: AN ADJUNCT TO CHEMOTHERAPY IN PNEUMONIA COMPLICATING CARDIAC DECOMPENSATION*

A Preliminary Report

JOHN OHNSTY, M.D.,† AND WILLIAM QUITMAN WOLFSON, M.D.‡

BROOKLYN, NEW YORK

A COMPLICATION frequently encountered in the administration of sulfonamides is kidney damage. If adequate urinary output is maintained and the urine is kept alkaline, the incidence of crystalluria, hematuria and frank renal damage is decreased.^{1,2} These measures are particularly important in patients with marked cardiac insufficiency, who tend to retain ingested water and to excrete small amounts of urine.

Sodium bicarbonate is most frequently used for alkalization. Modern therapeutics, however, stresses the primary significance of sodium retention in the development of cardiac edema and congestive heart failure.³⁻⁷ In cardiac decompensation, a regime promoting a negative sodium balance is considered advisable; it is not aided by the administration of sodium bicarbonate.

In the medical wards of this hospital are many patients in whom pneumonia accompanies and often precipitates cardiac decompensation. Rational therapy requires that both be treated simultaneously. This involves the administration of sulfonamides, the maintenance of adequate urinary output, urinary alkalization, restriction of sodium intake and promotion of diuresis, as well as the employment of other recognized measures.

Because the administration of sodium bicarbonate was considered to be incompatible with these objectives, other alkalizing agents were investigated. Many were tried and found to be unsatisfactory because of their tendency to cause gastrointestinal upsets when used in sufficiently large amounts. Potassium bicarbonate was finally chosen for clinical trial, since it was well tolerated in required doses.

METHOD OF STUDY

A group of patients with severe cardiac impairment and pneumonia treated with sulfadiazine and potassium bicarbonate were compared with a similar group treated with sulfadiazine and sodium bicarbonate. All the cases studied were admitted to the medical wards of the Greenpoint Hospital between December 1, 1943, and March 1, 1944. The criteria for inclusion in the study were survival for at least seventy-two hours after admission, cardiac decompensation of sufficient severity to be classified Grade III or IV according to the

specifications of the American Heart Association,⁸ demonstration of a lobar or bronchopneumonic process by clinical and radiologic findings and the absence of findings suggesting severe renal impairment or adrenal insufficiency. The last criterion was adopted as a precaution against potassium toxicity. Patients treated by us were given potassium bicarbonate; those treated by the other members of the house staff were given sodium bicarbonate.

All patients were given an initial dose of 4 gm. of sulfadiazine, followed by 1 gm. every four hours. In addition, they received an initial dose of 8 gm. of sodium or potassium bicarbonate, followed by 2 gm. of the chosen agent every four hours. To both groups fluids were given freely, and the patients were encouraged to drink at least 2500 cc. per day. Daily fluid intakes and outputs were measured, and the urinary pH was determined daily from a 6 a.m. specimen by the nitrazine method. Because of the difficulty of obtaining serum potassium levels, these could not be studied. In addition, many patients were critically ill and weight variations were unobtainable. Further routine orders included complete bed rest, a soft, low-salt, 1200-calorie diet, digitalization and other symptomatic measures as indicated, except diuretics.

RESULTS

Sixteen patients were studied over a total of sixty-five hospital days. Nine patients were treated with potassium bicarbonate (Table 1) and 7 with

maintained. The dosage of bicarbonate was not increased for patients not showing a urine of pH 7.4, but in further studies it is intended routinely to increase the dosage by 25 per cent to ensure alkalization.

Fluid intake. In most cases, it was not possible to achieve the desired daily intake of 2500 cc. The average fluid intake of patients treated with potassium bicarbonate was 2152 cc., and that of those treated with sodium bicarbonate was 1861 cc. The potassium-treated patients thus ingested an average of 291 cc. more than those in the control group.

Fluid output. No patient treated with sodium had an average daily output of over 1000 cc., whereas 7 of the 9 potassium-treated patients exceeded this figure. The average daily output was 1332 cc. in the potassium-treated group, but only 764 cc. in the sodium-treated group. Although, on the average, the former patients consumed 291 cc. more liquid than did the latter, they excreted 568 cc. more daily.

Intake-output differences. Since both groups of patients were maintained under identical conditions of diet, bed rest and environmental temperature,

any differences due to amounts of metabolic fluid derived from food and to quantities lost during respiration, from the skin and in the feces were not important and tended to offset each other.⁹ Under these conditions the patients showing a marked difference between intake and output were either retaining fluid in the body or excreting body fluid less rapidly than the others. If the body weights of both groups were gradually decreasing, it could be assumed that the observed intake-output difference was due to greater diuresis in one group than in the other.

Since most of the patients recovered from their congestive failure, it seems probable that the observed intake-output difference between the sodium-treated and potassium-treated groups depended on more rapid elimination of retained water by the latter. Unfortunately, daily weight determinations were impractical.

In this series the average difference between intake and output was 820 cc. a day for the potassium-treated patients and 1097 cc. for those treated with sodium. If the difference of 277 cc. a day between the two groups is interpreted as indicating more rapid excretion of excess water by the potassium-treated patients, this means that over the average period of treatment these patients excreted an average of 1250 cc. more retained fluid than did the sodium-treated patients. Only once in the sodium-treated group was the daily urinary output greater than the fluid intake, but outputs greater than intake were observed in one fifth of daily observations in the potassium-treated group.

DISCUSSION

There has been increasing realization that alkalization of the urine and maintenance of a satisfactory fluid output are essential during the administration of sulfonamides.^{1, 2} Approximately 1 per cent of patients receiving sulfadiazine show a significant increase in nonprotein nitrogen blood levels¹⁰; hematuria and crystalluria are frequent. Sodium bicarbonate given in doses equal to those of sulfadiazine and sulfathiazole reduces the incidence of crystalluria by 60 per cent. The amounts of sulfadiazine and of acetylsulfadiazine dissolved in normal urine at pH 7.5 are twenty times greater than those dissolved at pH 5.0.² Despite its theoretical advantage, sulfamerazine is not appreciably less nephrotoxic than sulfadiazine.¹¹ Alkalization is usually accomplished by giving 12 to 18 gm. of sodium bicarbonate a day. In most normal subjects the fluid output can be satisfactorily established at over 1000 cc. by an intake of 2500 to 3500 cc. a day.

The low-salt diet given these patients contains about 1.5 gm. of sodium a day. When 12 to 18 gm. of sodium bicarbonate are given daily, another 3.5 to 6.0 gm. of sodium is added. A patient with severe cardiac disease kept on a low-salt diet but

given sulfonamide and sodium bicarbonate receives from 5.0 to 6.5 gm. of sodium each day. This is appreciably larger than the 2-gm. to 4-gm. sodium content of the average American daily diet. Despite general recognition of the importance of sodium restriction in preventing and treating cardiac decompensation, the danger of administering such large doses of sodium bicarbonate to patients with severe heart disease has not been completely discussed by the advocates of alkali therapy.

The physician attempting simultaneous treatment of severe cardiac lesions and pneumonia has had to choose from several difficult alternatives. Sulfadiazine and sodium bicarbonate have been given, achieving alkalinization but risking the impeding of treatment directed toward improving the cardiac status and seriously decreasing the urinary output. Prescription of sulfadiazine without sodium bicarbonate is more considerate of the failing heart, but urinary acidity increases the threat of renal damage. If the fluid intake is limited to the amount required to overcome water retention induced by administered sodium, dangerous minimal fluid outputs result. Under satisfactory conditions patients with severe heart damage tend to have a small urinary output; under stress of infection the output may decline appreciably. This makes alkalinization indispensable when chemotherapy is given to such patients.

The efficacy of potassium bicarbonate in promoting adequate urinary output and rapid elimination of retained water depends on the special differential metabolism of sodium and potassium in cardiac decompensation. The primary factor involved is apparently the tendency of patients with chronic congestive failure to retain sodium.⁴ The cause is either endocrine or, more probably, renal; the exact mechanism is not understood, but essentially in all patients there is inability of a functionally damaged heart to meet the metabolic demands of an active person. With retention of sodium, water is held to maintain the constancy of the body's electrolyte pattern and, more importantly, the pattern of the extracellular fluid. Both the plasma volume and the volume of the extracellular, extravascular compartment are increased. Dilution of plasma proteins leads to increased production, with maintenance of normal oncotic pressure. Eventually, a continual increase in plasma volume leads to engorgement of the entire vascular bed, producing increased venous pressure, edema and clinical congestive phenomena. In acute cardiac decompensation other factors lead to increased venous pressure.³⁻⁵ In these patients, both acute and chronic factors were usually clearly implicated.

Pulmonary engorgement, deficient nutrition and the poor resistance of waterlogged, improperly oxygenated tissue lead to increased susceptibility to pneumonic processes. These infections induce secondary factors that further decrease cardiac

efficiency. Toxic myocarditis may reduce the already minimal cardiac reserve, and increased respiratory effort and accelerated metabolism of fever increase the load that must be borne. Lung involvement may lead to poor blood oxygenation, with resulting impairment of all oxidative processes, including those of the heart.

During pneumonia there is a decreased chloride output,^{12,13} and with this retention of fixed acid there is a concomitant tendency to retain fixed base. Since sodium is the most important mobile fixed base,¹⁴ this further accentuates the tendency to its retention, and decreases in sodium output result. Moreover, electrolyte concentrations of the extracellular fluid, particularly in lobar pneumonia, are temporarily stabilized at lower values.¹⁵⁻¹⁷ Even if no additional sodium were added to the body stores, additional water could be retained because of decreased sodium concentration per unit volume. It is not surprising that pneumonia so frequently causes striking impairment of the status of patients with injury to the heart.

Unlike sodium salts, which favor water retention, the salts of potassium have a definite diuretic action.^{7,18-20} Both in the normal state and in decompensation, ingested potassium is rapidly and quantitatively excreted, carrying water with it. The excretion of sodium is also somewhat accelerated because the sodium-conserving ability of the kidney is not absolute and because, with elimination of water, a certain amount of sodium must be excreted to defend the electrolyte pattern of the extracellular fluid.¹⁴

Reports of toxic effects attributable to therapeutic doses of potassium are infrequent, and no signs of intolerance were noted in this series. The oral administration of 40 gm. per day to patients with myasthenia gravis has produced no untoward effect.²⁰

The normal serum potassium level is from 3.4 to 4.8 milliequiv. per liter²⁰; elevated levels have been reported in shock, asphyxia, hemorrhage, intestinal obstruction and fistula, crush syndrome, pemphigus, severe adrenal insufficiency and uremia.²⁰⁻²² Only the latter two had to be considered in this study, and patients in whom either was suspected were excluded. In addition, electrocardiograms were studied, urinary outputs were carefully watched and pulse rates were frequently charted. The patients were observed and questioned about attacks of weakness and gastrointestinal disturbances. Potassium was to be discontinued if electrocardiographic changes, a pulse rate below 70, a urinary output below 600 cc. or an attack of weakness or gastrointestinal intolerance occurred; fortunately, it was never necessary to apply this rule.

In Addison's disease, there is a tendency to lose sodium and to retain potassium²³; if the salt intake is restricted and potassium is given, an acute exacerbation results.²⁴ Although patients were excluded

in whom adrenocortical insufficiency was suspected, it is unlikely that our regime could have induced acute adrenal crisis in the decompensated cardiac patients. Such persons to some extent have an electrolyte metabolism opposite to that of the Addisonian; they have ample sodium reserves, their adrenal glands are not impaired, and they tend to sodium retention rather than to sodium depletion.

Toxic effects have been reported in severe renal insufficiency when potassium was given; these consisted of intermittent bradycardia, attacks of weakness and electrocardiographic findings of partial heart block with T-wave inversions.²⁵ Retention of potassium in uremia is not due merely to the extreme renal damage, for a case has been reported in which uremia was accompanied by potassium depletion.²⁶ The situation is somewhat analogous to that of renal rickets; in the usual form, there is hyperphosphatemia and hypocalcemia, but rarely hypercalcemic renal rickets is seen.²⁷ A complex metabolic disturbance occurs in renal insufficiency, but for our purposes it was felt safest to exclude these cases.

If subsequent employment of mercurial diuretics is contemplated, alkalization is terminated as soon as possible in order not to decrease their efficiency.^{28, 29}

Actually, the 12 gm. of potassium bicarbonate given each day represents less potassium than the 10 gm. of potassium chloride frequently used as a daily diuretic dose. Together with the low reported toxicity, adverse effects seem unlikely even without the precautions adopted in this study.

SUMMARY

Potassium salts have long been used as diuretics. Employing conventional dosage, we have attempted to utilize the diuretic effect of potassium and the alkalizing effect of its bicarbonate to facilitate treatment of patients with severe heart damage who were receiving sulfadiazine for pneumonia. Patients so treated drink somewhat more liquid than do those given sodium bicarbonate, but they excrete almost twice as much urine and eliminate over 250 cc. more of retained fluid each day. By promoting excretion of retained water and sodium, potassium facilitates the re-establishment of cardiac compensation.

At present, we give potassium bicarbonate to all patients whose cardiovascular status is classified as Grade III or IV whenever they receive sulfonamides. Its use is being extended to milder cases as pro-

phylaxis against decompensation. Ten grams given with the initial dose of sulfonamide and gm. every four hours thereafter until twenty-four hours after discontinuance of chemotherapy.

Although apparently of low toxicity, potassium bicarbonate is not used when severe renal impairment or adrenocortical insufficiency is suspected.

FULMINATING MENINGOCOCCEMIA

Demonstration of Intracellular and Extracellular Meningococci in Direct Smears of the Blood

WILLIAM P. BOGER, M.D.*

BLUEFIELD, WEST VIRGINIA

IT IS the purpose of this paper to call attention to the unusual finding of meningococci by direct examination of the peripheral blood smear, in a case of fulminating meningococcemia that may also have been a case of the Waterhouse-Friderichsen syndrome.

CASE REPORT

A 27-year-old woman (M. C. V. A-18280) was admitted to the hospital on January 29, 1943. She stated that she was traveling by bus from Atlanta, Georgia, to Elmira, New York, when she began to feel "sore all over," apparently from sleeping in a cramped position. In the course of a few hours there developed a dull headache, stiffness of the neck, slight nausea and finally persistent vomiting. Because of the vomiting the patient left the bus and presented herself at the Emergency Ward of the hospital.

The patient was able to give a clear account of herself, and stated that prior to 8 hours before admission she had been perfectly well. The only significant point in the recent history was the ingestion of ground meat 2 days previously.

Examination showed a well-developed and well-nourished woman lying comfortably in bed. The temperature was 102° F., the pulse 90, the respirations 20, and the blood pressure 100/60. The pupils were equal and reacted to light and accommodation. The ocular fundi showed no papilledema. The pharynx was slightly injected and the patient mentioned a slight feeling of scratchiness. The chest was clear. The heart was normal in size, rate, rhythm and sounds. The neck was supple and no stiffness was noted. The reflexes were equal and active, the Kernig and Brudzinski signs were absent, and the Babinski responses were plantar. The muscles of the entire body were tender on palpation, especially in both lower legs. There was no edema.

The patient appeared to be suffering from influenza, but the diagnoses of trichinosis and meningococcal meningitis were also entertained. Trichinosis was considered because of the ingestion of ground meat of questionable origin, and meningitis because of the prevalence of meningococcal infections.

Examination of the blood revealed a hemoglobin of 76 per cent (Sahli). The white-cell count was 11,900, with 99 per cent neutrophils, most of which showed marked toxic granulation. A lumbar puncture was done in the 4th lumbar interspace and clear fluid under 100 mm. of water pressure was obtained. The cell count was 7 lymphocytes per cubic millimeter. No organisms were seen on microscopic examination of the fluid.

Four hours later a venipuncture was done to obtain a specimen for routine chemical study, and during this procedure several petechiae were noticed on the forearm. No other petechiae were observed, and in view of the normal spinal-fluid findings no significance was attached to this observation.

The following morning the patient was obviously more ill, complaining of severe pains in the muscles and joints and presenting a generalized purpuric rash, with lesions varying in diameter from 0.5 mm. to 2 or 3 cm. These lesions were not raised above the surface of the skin, were nontender and did not fade on pressure. The larger lesions were deep purple, and several lesions of this type were located at the fingertips, simulating closely the appearance of gangrene. Purpuric spots were present over the face, the extremities, the body, the conjunctivas and the oral mucous membrane. A diagnosis of fulminating meningococcemia was at once made. The patient was still mentally alert but was

frankly apprehensive, whereas the night before she had regarded herself as only mildly ill.

A blood specimen was taken for culture and examination and at the same time 10 gm. of sodium sulfadiazine was given intravenously. The temperature was 103° F., the pulse 110, and the respirations 24. The white-cell count again revealed 99 per cent neutrophils. There were few adult neutrophils as compared with the number of premature forms, and on stained smears, 7 per cent of the polymorphonu-

FIGURE 1. Photomicrograph of a Polymorphonuclear Leukocyte Containing Phagocytized Meningococci (x900).

clear cells were found to contain phagocytized gram-negative diplococci (Fig. 1). Extracellular organisms were also observed.

At noon the patient was given a 500-cc. transfusion. Antimeningococcus serum was not available. An infusion of 1500 cc. of 5 per cent glucose in physiologic saline solution was given, but the patient became steadily worse. The temperature declined, the pulse rate rose, and the blood pressure fell to 60/40. Four cubic centimeters of cortical extract was given intramuscularly. The purpuric spots previously noted were seen to enlarge and new petechiae appeared.

That evening the patient presented a startling appearance. Intracutaneous extravasations too large to be covered by the outspread hand were present over the thorax and extremities, and extravasations of smaller size were present on the face. The patient could not be roused. The temperature was 99° F., the pulse 140, and the respirations 30. It was believed that the patient presented the classic clinical picture of the Waterhouse-Friderichsen syndrome.

During the night she gradually went into a state of vasomotor collapse, and in spite of further infusions of 5 per cent glucose in physiologic saline solution and 2 cc. of cortical extract, she died at 6.25 a.m. on the following day.

Permission for autopsy was not granted, so that doubt remains whether there were adrenal hemorrhages, as required to fulfill the criteria of the Waterhouse-Friderichsen syndrome. The duration of the illness was approximately 47 hours.

The diplococci seen in the blood smears were cultured from the blood stream and found to be meningococci.

DISCUSSION

Fulminating meningococcemia runs its course in a matter of hours, usually less than forty-eight. Of this form of meningococcal infection, Herrick¹ has

*Director, Medical Department, St. Luke's Hospital, Bluefield, West Virginia; formerly, medical resident, Medical College of Virginia, Hospital Division, and instructor in medicine, Medical College of Virginia, Richmond.

said, "No other infection so quickly slays." In this disease the diagnosis must be made as promptly as possible and treatment instituted at once, for if the development of the clinical picture is awaited, the hope of survival is negligible. The length of time required for blood cultures reduces their value as a clinical aid²; as in this case, they are frequently of only academic and post-mortem interest.

McLean and Caffey³ found meningococci in smears taken from the petechiae and purpuric extravasations seen in many cases of meningococcal infection. This procedure is simple and should be oftener resorted to. Unfortunately, many cases of meningococcal meningitis fail to develop a rash, and in fulminating meningococcemia the type of purpura is in itself almost diagnostic.

Herrick⁴ and Adams² cursorily mention the finding of meningococci in the peripheral blood. Boone and Hall,⁵ Marangoni and D'Agati,⁶ and Kwedar⁷ have encountered cases and presented photographs of meningococci in the peripheral blood. Thomas⁸ mentions that in 6 of 12 fatal cases of fulminating meningococcemia organisms were seen in the peripheral blood. It is thus seen that a diagnosis from the blood smear is possible.

It is not suggested that every blood smear made in an acutely ill case should be scrutinized for phagocytized gram-negative organisms, but such examination is worth consideration when there is meningitis in the community, when there is objective muscle tenderness, and when a gripe-like or influenza-like syndrome is presented in combination with a leukocyte count that is predominantly polymorphonuclear. With reference to these points, it is impossible to be too alert in suspecting meningococcal infections when the disease is established in a community. The muscle tenderness that was present in this case was not sufficiently appreciated, but from observation of other cases of meningococcal septicemia it is apparent that Dickson et al.⁹ are correct in their statement that this is a symptom that differentiates meningococcal septicemia from other forms of acute infection. The type of the tenderness is clearly different from the myalgia complained of in the usual case of acute febrile illness. The leukocytic response is likewise instructive, and Herrick⁴ says, "Excepting lobar pneumonia no other acute infection is accompanied by such early and profound leukocytic reaction, 50,000 to 60,000 with an average of 90 per cent polymorphonuclears."

Its use as a bacteremia so overwhelming as to present free in the blood stream in such numbers can be found on a direct blood smear hope of recovery. The finding has been only in fatal cases.⁵⁻⁸ As has been pointed out, if routine examination of the blood could establish the diagnosis, valuable time and therapy instituted in time to save the patient.^{5, 6}

The suggestion that the examination of the direct blood smear in the occasional case may be worthwhile has added weight inasmuch as, according to Thomas,⁸ "It seems fairly certain now that every clinical meningococcal infection with the possible exception of a variety of infection of the upper respiratory tract consists at some stage of an invasion of the blood stream by the causative organism." This concept is only now being generally accepted, but Herrick⁴ clearly stated it in 1915. Indeed, the blood stream may be the only site of the infection. "Three patients," he states, "each having a blood culture positive for meningococci of Group I, recovered spontaneously without drug or serum therapy before the culture was known to be positive."

In speaking of fulminating meningococcemia, the subject of the Waterhouse-Friderichsen syndrome is called to mind. The terms are not synonymous. The Waterhouse-Friderichsen syndrome is an overwhelming septicemia that produces purpuric subcutaneous extravasations and bilateral adrenal hemorrhages. Although it is true that meningococcal infections usually produce this syndrome, overwhelming sepsis due to other organisms occasionally gives rise to similar adrenal hemorrhages. Furthermore, not all patients who die with the clinical picture of the Waterhouse-Friderichsen syndrome present adrenal hemorrhages. Thomas⁸ remarks their absence in 6 of 23 autopsied cases. Hence it seems ambiguous to use the term "recovery" in speaking of the Waterhouse-Friderichsen syndrome since the adrenal hemorrhages can only be inferred if the patient recovers. Clinically the term "fulminating meningococcemia" seems preferable to "Waterhouse-Friderichsen syndrome," and if the latter has any usefulness it should be restricted to pathological discussions.

The bilateral adrenal hemorrhages seen in these fulminating septicemias have suggested that the mechanism of death is that of acute adrenal failure. The hypotension, hypothermia or hyperthermia, vascular collapse, abdominal pain, vomiting and cadaveric cyanosis — incident to the intracutaneous extravasations — are indeed similar to the findings in the crisis of Addison's disease. There are, however, in the literature no significant data concerning electrolytes, blood sugar, nonprotein nitrogen and hematocrit readings in cases of fulminating septicemia. Aegerter¹⁰ in reviewing the subject of the Waterhouse-Friderichsen syndrome calls attention to the paucity of such data. This is not to be wondered at, since the short course of the disease, the uncommonness of the cases in adults and the imperativeness of treatment leave little time for investigation. In the case reported herein the blood sugar was 89 mg. per 100 cc., and the nonprotein nitrogen 44 mg., the latter figure being somewhat elevated. It seems doubtful that changes in electrolyte or carbohydrate metabolism drastic

organisms that they offer little reported on however can be

enough to produce death would occur in a matter of an hour or two. Especially doubtful does this explanation of death become when one considers that the experimental animal withstands complete surgical ablation of the adrenal glands for a much longer period than the forty-eight hours that is usually set as the upper limit of survival in fulminating meningococcemia.

On the other hand, the suggested treatment of these cases with massive doses of cortical extract, adrenalin, intravenous glucose and saline solutions and blood transfusions¹⁰ seems worthy of trial. This type of therapy was used in the present case, but the amount of cortical extract was insignificant and the amounts of intravenous fluids were small. Loeb¹¹ states that 50 to 75 cc. of commercial cortical extract must be used every twenty-four hours in the treatment of crisis in Addison's disease, and a comparable dosage seems to be indicated in treating fulminating meningococcemia.

The hypothesis that death is due to acute adrenal failure is attractive but not proved. The additional fact that some patients die of fulminating meningococcemia without showing adrenal hemorrhages indicates that however undesirable the term "toxemia" is, there is still a place for this concept. In a bacteremia with organisms free in the blood stream in enormous numbers the products of their metabolism in terms of toxins are certainly appreciable, which suggests that antibacterial and antitoxic serums should be used in these cases. Thomas,⁸ although admitting that the subject is controversial and that the majority opinion is indifferent to the use of antiserum, states, "There is one group of patients who seem to have been benefited by meningococcus antitoxin, namely, . . . [those with] septicemia."

It may yet be established that the subcutaneous extravasations seen in cases of fulminating meningococcemia are due to a vascular toxin. Thrombosis of small vessels in the adrenal glands by clumps

of meningococci has been demonstrated, but proof that the skin lesions are due to a similar mechanism has not been forthcoming.

SUMMARY AND CONCLUSIONS

A case of fulminating meningococcemia has been presented.

The term "Waterhouse-Friderichsen syndrome" appears to be ambiguous when applied to the living patient.

The concept of acute adrenal failure as the mechanism producing death is attractive, although not proved, but certain measures of therapy useful in combating the crisis of Addison's disease may, nevertheless, be applicable in fulminating meningococcemia.

In this type of meningococcal infection antiserum should probably be used.

In certain cases the examination of the blood smear may establish the diagnosis more promptly than is possible by any other means.

MEDICAL PROGRESS

THORACIC SURGERY (Concluded)

JOHN W. STRIEDER, M.D.*

THE ESOPHAGUS

ALTHOUGH the esophagus has been called "the last frontier of surgery," notable advances have been made in the surgical treatment of various lesions of this organ since the publication of the excellent and exhaustive review of the subject by Bird⁴⁸ that appeared in 1939. The achievements in congenital atresia and carcinoma have been outstanding.

Congenital Atresia

Vogt⁴⁹ classifies the anomaly of congenital atresia as follows: complete absence; atresia without tracheal fistulas; atresia with fistulas between the trachea and the esophagus, situated between the upper segment and the trachea, between the lower segment and the trachea or between both segments and the trachea. In this classification the second and particularly the third type constitute the great majority of reported cases that are being treated surgically with increasingly encouraging results.

The constant symptoms, consisting of regurgitation of milk and mucus with attacks of choking, cyanosis and coughing, occur when the infant is first fed. A plain roentgenogram of the abdomen shows the stomach filled with air, thus proving the presence of tracheoesophageal fistula, which occurs in about 75 per cent of the cases of atresia, as distinguished from the far less frequent complete or incomplete atresia of the esophagus without a fistula which occurs in 25 per cent.⁴⁸ As suggested by various authors,^{50,51} diagnosis can be verified simply and safely by passing a small catheter into the esophagus. This proceeds readily into the stomach in any normal infant. If it meets obstruction at the level of the thoracic inlet, — this may be verified by fluoroscopy, — the diagnosis can be definitely made. With diagnosis thus established, attempts to visualize the blind pouch by injecting barium or iodized oil should not be made, since they almost always result in the introduction of opaque material into the lungs, with resultant pulmonary complications. Once the diagnosis is made, unless there are other anomalies that contraindicate operation, this should be proceeded with at the earliest feasible moment to prevent the frequent complication of aspiration pneumonia.

Although the ideal treatment is the ligation and division of the fistula with re-establishment of

esophageal continuity, this cannot always be achieved, and other and indirect measures have been devised and successfully carried out to meet such situations. To Leven⁵² must go the credit for the first successful extrapleural ligation of a tracheoesophageal fistula with cervical esophagotomy, which he performed in stages from January 5 to March 27, 1940, after a preliminary gastrotomy. At almost the same time, Ladd⁵⁰ independently worked out an essentially identical procedure that was equally successful. According to Humphreys⁵¹ both these patients and several others operated on since that time by the same surgeons are still living at more than four years of age. With this plan of ligation of the fistula, esophagotomy and gastrotomy, an anterior thoracic esophagus is eventually constructed of skin by a series of plastic procedures, so that ultimately the patient conveys food and liquids from mouth to stomach by means of esophagodermatogastrotomy.

As stated above, the theoretical ideal is the establishment when possible of esophageal continuity by direct anastomosis. The first reported attempt was that made by Shaw⁵³ in 1939. Although the operation was successfully performed, a reaction from an elective transfusion resulted in death on the twelfth postoperative day. Haight and Townsley⁵⁴ report the first case successfully treated by extrapleural ligation of the tracheoesophageal fistula and end-to-end anastomosis of the esophagus.

In a recent personal communication, Dr. C. Haight states that he has been able to anastomose the two segments of the esophagus in 16 patients, 6 of whom are living; all of them have a patent esophagus. Five of these take all their feedings by mouth without difficulty, but in 1 case there is a high-grade stenosis for which retrograde dilatations are done from time to time. The sixth patient has a wide-open esophagus, but a recurrent tracheoesophageal fistula has been discovered. The oldest living patient was operated on three years ago and is doing extremely well. The youngest living patient has passed nine months since the operation.

Stricture

Simple severe stricture of the esophagus, the result of the ingestion of caustics or other severe cicatrizing trauma, has long been a discouraging problem. Frequent bouginage, a gastrotomy life or both are frequently the lot of these patients, many of whom are children or young adults otherwise in excellent health. Although the construction

*Assistant professor of thoracic surgery, Boston University School of Medicine; visiting surgeon in charge of thoracic surgery, Massachusetts Memorial Hospitals; visiting surgeon for thoracic surgery, Boston City Hospital.

if an anterior thoracic esophagus from skin has frequently been accomplished with satisfactory functional results, the method has many disadvantages. Not the least of these is the appearance of fistulas at the site of anastomosis of the skin tube with the cervical esophagus and especially with the stomach. Many ingenious technics have been devised, but the constant regurgitation of acid gastric contents into the skin tube of the reconstructed esophagus sets up an irritation that sometimes results in ulceration of the tube and formation of a fistula at the anastomosis. These fistulas are difficult to heal and therefore usually impede satisfactory reconstruction of the esophagus.

Recently Yudin,⁵⁵ director of surgery of the Sklifasovski Institute for Traumatic Diseases in Moscow, has reported on the surgical construction of an artificial esophagus in 80 cases. He recommends drawing a segment of jejunum through an anterothoracic subcutaneous tunnel as high as the angle of the left inferior maxilla, where it is immediately or at a subsequent stage anastomosed with the cervical esophagus. This author states that in his opinion a total intestinal plastic operation is the one of choice and is practicable in strictures located below the middle of the cervical section of the esophagus. The construction of the new esophagus should be carried out in two stages: exteriorization of the intestine—through a skin tunnel—up to the neck and direct anastomosis with the cervical esophagus. He believes that the operation should not be completed in one stage because of the tremendous risk of infecting the whole subcutaneous tunnel at the point of anastomosis of the esophagus and the jejunum. By July, 1943, Yudin had created artificial esophaguses in 88 cases, total intestinal esophagoplasties being performed in 21. The direct operative mortality was 2.3 per cent.

Carcinoma

In 1940, Garlock⁵⁶ wrote, "Heretofore, the diagnosis of carcinoma of the esophagus was tantamount to signing the patient's death warrant, and the physician advised palliative measures consisting of gastrostomy, radiation therapy or both." Because of the pioneer work and enthusiasm of this surgeon and many others, such a situation no longer obtains, and many probable cures have been accomplished in a disease that was once held to be beyond help and hope. The successful surgical resection of a cancer-bearing portion of the esophagus, particularly the lower and midportions, has been so frequently reported in the past five years that it may now be accepted as having passed beyond the stigma of a surgical stunt. It has been estimated that 5 per cent of all malignant disease occurs in the esophagus, with the proximal third involved in 18 per cent of these cases. Experience with radiation therapy

has given no encouragement, and surgery has afforded the only hope of a cure, so that the surgeon must do all in his power to establish an earlier diagnosis.

It has been customary to divide the esophagus into three parts, and to speak of the upper, middle and lower thirds. Churchill and Sweet⁵⁷ believe that it is more useful to divide it into fourths, the second and third fourths being thought of as the middle half. From the point of view of surgical management they consider three zones. Zone 1, the upper fourth, extends from the base of the neck to the superior surface of the aortic arch. Zone 2, the middle half, includes that portion extending from just above the aortic arch to just below the level of the inferior pulmonary veins. Zone 3 includes the lower fourth of the thoracic esophagus, the cardiac orifice of the stomach and the adjacent few centimeters of the stomach, as well as the fundus.

Carcinoma of upper esophagus (Zone 1). Bird⁵⁸ states that two factors appear to have contributed to the recent lack of interest in carcinoma of the upper third of the esophagus, as compared to the enthusiasm shown in the attack on growths in the middle and lower thirds. In the first place, the cases are not so frequent; secondly, the field of operation is ill defined, and the lesion most frequently encountered—Trotter's type of hypopharyngeal epithelioma occurring in young and middle-aged women—is prone to be neglected by both the laryngologist and the thoracic surgeon. Hudson⁵⁸ reports 2 cases of carcinoma of the proximal portion of the upper third of the esophagus that illustrate the value of complete removal of the lesion and the disappointment that may follow anything short of complete removal. The lesions are so intimately associated with the larynx or involve it in such a manner that both the esophagus and the larynx must be removed if a cure is to be expected.

The results of surgical excision in the upper esophagus have not on the whole been encouraging, but they are good enough to stimulate continued attempts at cure and perfection of technics. Radiation is only of palliative value.

Carcinoma of midesophagus (Zone 2). Approximately four fifths of the lesions in carcinoma of the esophagus occur in its thoracic and abdominal portions.⁵⁹ In general it may be said that the greater part of the thoracic esophagus must be removed if a carcinoma of the middle third is to be cured, and the Torek⁶⁰ operation or some modification of it has usually been employed. Up to 1939, the only certain cure of a carcinoma of the midesophagus was obtained in 1913 by Torek,⁶⁰ whose patient lived for twelve years after operation and died of pneumonia without recurrence, as shown at autopsy. There are undoubtedly others, since Garlock⁶¹ in 1941 stated that one of his patients was alive almost five years after resection. This operation entails preliminary gastrostomy and cervical

esophagostomy at the time of the transthoracic resection of the carcinoma, with the connection of these two stomas contemplated at a later date to re-establish continuity, usually by an anterior thoracic esophagus of skin.

There are many unsettled technical problems involved that need not be discussed in this review.

Churchill and Sweet⁵⁷ report 9 cases, with 3 patients alive and well. There were only 2 postoperative deaths. Ochsner and DeBailey⁵⁸ report 2 cases, with postoperative deaths in both. Phemister⁶² reports resection and cervical esophagostomy in 4 cases, with 3 survivals. Wu and Loucks⁶³ have operated on 4 patients with carcinoma of the midesophagus, with 2 survivals. Santy et al.⁶⁴ explored 6 patients and were able to resect the esophagus in 2, both of whom survived. Allison⁶⁵ describes 4 cases of esophageal carcinoma treated by the excision of the thoracic esophagus in 3 and of the stomach and abdominal esophagus in 1. All the patients survived the operation, but none lived longer than one year. Franklin⁶⁶ successfully removed the thoracic esophagus for cancer in 2 cases. One patient is well, and the other died thirteen months after operation. Carter⁶⁷ operated on 2 patients with carcinoma of the lower third by a modified Torek technic with 1 death in the hospital from meningitis and 1 recovery. Garlock⁶¹ has done 13 Torek or modified Torek operations with 6 deaths. One patient is alive almost five years later and another thirteen months later.

In a recent communication Garlock⁶⁸ states that he believes that greater mobility of the stomach can be obtained by dividing the branches of the left gastric artery so that the stomach can be pulled higher into the left pleural cavity without tension. He has also brought the proximal end of the esophagus anterior to the arch of the aorta and performed esophagogastrostomy in cases in which the Torek operation would formerly have been necessary. We have repeated this procedure at the Massachusetts Memorial Hospitals and have been gratified at the ease with which esophagogastrostomy can be performed with the aid of these maneuvers. It seems likely that continuity between the stomach and the esophagus can be established within the thorax in a greater number of middle-third (Zone 2) cancers by means of this technic than has hitherto been thought possible.

Carcinoma of lower esophagus and upper end of stomach (Zone 3). Carcinomas arising in the fundus or cardia of the stomach and extending to involve the lower esophagus pose an almost identical problem as do tumors arising in the lower esophagus itself, and operations on both types of lesions will be considered together.

According to Bird,⁴⁸ in spite of the fact that Biondi (1895), Sauerbruch in his early work and Janeway and Green (1910) had worked out an appar-

ently satisfactory endothoracic esophageal-gastric anastomosis on dogs and cadavers; no successful human cases were recorded until Ohsawa's in 1933.

At the 1938 meeting of the American Association for Thoracic Surgery, Adams and Phemister reported the first successful thoracic esophagogastrostomy for carcinoma performed outside of Japan. This was for squamous-cell carcinoma of the lower third of the esophagus. The resection followed careful preparation by experimental work on dogs and the authors had profited by experiences derived from a previous unsuccessful case.⁴⁸

Since that time, an increasing number of successful cases is being recorded in the literature. In 1940, Garlock⁶⁶ reported resection and esophagogastrostomy in 2 cases with 1 recovery. He also performed radical resection and intrathoracic esophagogastrostomy in 3 cases of carcinoma originating in the cardia, and stated that he was convinced that the only logical method of treating cancer in this situation was by the transthoracic transdiaphragmatic route. In the same year Carter et al.⁷⁰ reported 2 successful cases of transpleural esophagogastrostomy for carcinoma of the esophagus and for carcinoma of the cardiac portion of the stomach. Ochsner and DeBailey⁵⁹ have reported 2 cases, with 1 survival. Phemister⁶² states that resection and esophagogastrostomy were performed in 4 cases, in 2 of which carcinoma was primary in the esophagus and in 2 primary in the stomach. One patient in each group survived the operation. Wu and Loucks⁶³ have operated in this manner on 6 patients with carcinoma involving the stomach or esophagus or both, with 4 survivals. Garlock⁶¹ performed transthoracic resection with esophagogastrostomy for adenocarcinoma of the cardia and squamous-cell tumors of the distal esophagus. There were 15 cases with 6 deaths, an operative mortality of 40 per cent. Churchill and Sweet⁵⁷ report 11 cases in which resection and esophagogastric anastomosis for carcinoma of the stomach or lower esophagus was performed. There was 1 postoperative death, a mortality of only 9 per cent. Two of the survivors died of recurrent disease, but all the remainder were well and free from symptoms for from three months to two and a half years after operation.

Garlock,⁶¹ in summary, states that the general problem of the surgical treatment of cancer of the esophagus can, on the basis of his experience, be reduced to exact figures. The average patient with cancer of the middle third stands a 54 per cent chance of surviving the operation and a 30 per cent chance of living for over one year. With squamous-cell cancer of the distal third, the patient has a 70 per cent chance of surviving the operation and an almost 100 per cent one of living for over two years. In the group of adenocarcinoma of the cardia, the probability of operability is only 37

er cent; there is a 60 per cent chance of operative survival and an 80 per cent probability of living or over one year.

As may be noted from the foregoing reports, there has been a great advancement in the treatment of this disease by these methods. It is reasonable to expect even greater improvement in operability, mortality and survival with earlier diagnosis and greater experience in operative management.

THE THYMUS GLAND

There is no organ concerning which physicians have so little exact knowledge as the thymus gland. There has recently been some evidence of a relation between abnormalities of this gland and myasthenia gravis.⁷¹

Stimulated by the work of Blalock et al.,⁷³ who in 1941 reported the effects of removing the thymus gland from 6 patients with myasthenia gravis, the first concerted attack on this problem, Sloan⁷² examined 350 thymus glands. These included approximately 200 specimens removed during routine autopsies at the Johns Hopkins Hospital and 150 specimens removed from patients who died suddenly and were autopsied at the city morgue. Sloan's findings, in part, are as follows:

Examination of 10 thymus glands, none of which contained a tumor, removed at operation from patients with myasthenia gravis showed constant changes. In all there was some age involution and an increase in the number of lymphocytes present in the thymus. In 7 cases, abnormal numbers of lymphoid follicles with germinal centers were present in the medulla. There was no epithelial hyperplasia and no constant change in the character and number of Hassall's corpuscles. In 6 autopsied patients with myasthenia gravis who had not undergone operation there was no generalized lymphoid hyperplasia. The changes found in the thymus gland in myasthenia gravis were not part of such a generalized lymphoid hyperplasia.

Clagett and Root,⁷¹ reporting on 10 cases in which thymectomy was performed, with 1 death, state that their results have been satisfactory enough to warrant further employment of this operation in cases of myasthenia gravis and, at times, even in cases in which no thymic enlargement is demonstrable by x-ray. They discuss the advantages of the three approaches that they have used — transcostal, posterolateral and sternal splitting.

Hardy and Bradshaw⁷⁴ summarize the literature on the value of surgery in 132 cases of proved myasthenia gravis, including 3 of their own. Approximately 50 per cent have shown improvement. They believe that more cases must be operated on before conclusions can be drawn.

At the 1944 meeting of the American Association for Thoracic Surgery, Blalock⁷⁵ reported on the effects of thymectomy performed on 20 patients with severe myasthenia gravis. Only 2 of these

patients had tumors of the thymus. Approximately 8 showed striking improvement, whereas in the others there was only slight if any improvement.

Obviously much work remains to be accomplished on this fascinating subject. If a relation between the thymus gland and myasthenia gravis exists, there appears to be some factor that is not as yet understood.

THE HEART

In most cases of chronic heart disease, the physician is not able to effect a complete cure but is able to prolong life and to make the patient more comfortable. There are, however, some diseases of the heart or of the structures indirectly affecting it that respond brilliantly to surgical therapy. These conditions constitute only a small percentage of the total, but this does not minimize the importance of diagnosing and treating them (Blalock⁷⁶). It is with the surgical types of heart disease in which cure can often be effected that this review will be concerned.

Patent Ductus Arteriosus

The first attempt at obliteration of a patent ductus arteriosus was reported by Strieder⁷⁷ in 1937. The patient was operated on at the suggestion of Dr. Ashton Graybiel⁷⁸ and was already ill with subacute bacterial endarteritis. Death occurred on the fourth postoperative day and was due to acute dilatation of the stomach. The first successful case of surgical ligation of a patent ductus arteriosus was reported by Gross and Hubbard⁷⁹ in 1939. Since that time many successful cases have been reported, so that the operation has been established as a sound and rational procedure.

Burwell⁸⁰ has tentatively suggested the indications for the performance of this operation. These indications, which are generally accepted by most writers on this subject, are as follows: the presence of important limitation or actual heart failure, the demonstration that the patent ductus arteriosus is interfering with normal growth, or the presence of subacute bacterial endarteritis; and the demonstration of uncomplicated patency in itself, because of the probable utility of the operation in preventing progressive overwork of the heart and in preventing bacterial endarteritis in a young person. The latter constitutes a strong suggestion that operation should be considered.

In 1940, Jones, Dolley and Bullock⁸¹ reported the ligation of 13 cases, with 1 death. In 1942, Humphreys⁸² reported 16 cases, with no operative deaths. There was 1 late death from complications arising from the presence of a postoperative aneurysm of the ductus. Six patients were operated on because of subacute infection of the blood stream. Three of these were apparently cured, 1 was still in the postoperative period, 1 had died, and 1 still had positive blood cultures.

Touroff,⁸³ reporting on a series of 10 cases of patent ductus arteriosus complicated by infection, states that cures occurred in 7. There were 2 deaths from accidental hemorrhage and 1 failure ascribed to vegetations on the aortic valve. Thus, among 8 operative survivals there were 7 recoveries and 1 failure.

There have been many other reports of small series and single successful cases.

It seems likely that the operative mortality will be less than 10 per cent in the hands of experienced and skillful operators. Improvements in technic will undoubtedly lower this rate.

Gross⁸⁴ has recently described a carefully worked-out technic whereby in 14 cases he has successfully completely divided the ductus arteriosus. This, of course, is the method of choice, since it eliminates the possibility of recurrences by recanalization when the ductus has been treated by single or even double ligation.

Coarctation of Aorta

In an intriguing paper, Blalock and Park⁸⁵ describe 43 animal experiments during the course of which they divided the aorta below the arch and, turning down the left subclavian artery, anastomosed it with the distal portion of the aorta. There were 10 survivals of several months or longer. The authors suggest the possibility of using the common carotid artery in man to bridge a coarctation of the aorta, but believe that it should be considered only in human cases in which the outlook is very grave, since many patients with coarctation of the aorta have a fairly long life expectancy.

Trauma

In recent years there have been many reports of successful suture of penetrating wounds of the heart.⁸⁶⁻⁹⁶ One of the largest series is that of Bigger,⁸⁶ who operated on 17 patients at the Medical College of Virginia Hospital. Eleven recovered, and 6 died. Bigger also collected, by questionnaire, reports of 141 patients operated on by other surgeons and found that 71 recovered and 70 died, a recovery rate of approximately 50 per cent, which he believes more nearly approaches the actual recovery rate than do the figures collected from the literature. Elkin⁸⁷ reports 38 patients with heart wounds operated on by him or his resident staff. Of these, 22 recovered and none of them had any residual symptoms referable to the injury.

Blalock and Ravitch⁹⁶ discuss whether the total of successful end results would not be greater if a more conservative policy regarding immediate operation were adopted in cases in which there is no active bleeding through the chest wound or into the pleural cavity. To put the matter otherwise, may operation be delayed and aspiration of the pericardium be used in cases in which the symptoms are due to tamponade rather than to continued

active bleeding? Even if one decides to pursue this policy, facilities for immediate operation should be available and tamponade should not be allowed to persist for over two hours. If blood accumulates after aspiration, operation is indicated. This coincides with the following directions, recently prepared for medical officers in the United States Army relative to the treatment of penetrating heart wounds with resulting tamponade: aspirate the blood from the costoxiphoid route, if possible; repeat the aspiration if there is a recurrence; and if there is another recurrence, perform a cardiac raphy through an extrapleural exposure. Cases falling into this category, which have been or could have been treated conservatively, have been reported by Bigger,⁸⁶ Elkin⁸⁷ and Strieder.⁹⁷ It seems more likely, under these circumstances, that a coronary artery or vein has been wounded and the myocardium incised for only a portion of its thickness rather than that a complete penetration of the myocardium has occurred.

I have been asked by medical officers in the Army course in thoracic surgery how one can be sure, on performing pericardicentesis, that the aspirating needle is in the blood-filled pericardium and not in one of the heart chambers. This question is not so naïve as it might appear at first glance, since I have seen blood aspirated directly from the heart of unsuspectedly large proportions with the operator under the impression that he was aspirating a hemopericardium, which actually was not present. As in any procedure, one gains facility only with experience, but if the needle is advanced slowly by the costoxiphoid route, a definite sensation is transmitted to the operator as the pericardium is perforated and at this point blood is obtained once as the plunger is withdrawn. If the needle is cautiously advanced a short distance farther, the movements of the heart can be felt against the tip of the needle, which should then be withdrawn to the original depth at which blood was first obtained.

It seems, however, that not operating on a patient with a wound of the heart is an extremely hazardous course to follow. Nelson⁹⁸ believes that in all cases of penetrating thoracic wounds in which it cannot be determined positively that the wound has not reached the heart should have exploration performed.

Olim and Hughes⁸⁸ and Zerbini⁸⁹ have each reported a case in which it was necessary to ligate the left anterior descending coronary vessels to repair stab wounds of the right ventricle. Both patients recovered, and follow-up indicated that they were unaffected by the procedure.

Nonpenetrating wounds of the heart resulting in contusion and rupture have been discussed by Elkin,⁸⁷ Bright and Beck,⁹⁹ Beck,¹⁰⁰ Leinoff¹⁰¹ and Barber.¹⁰² These authors agree that this type of injury is a frequent, though often overlooked, cause

of death. Compression of the heart between the sternum and the bodies of the vertebrae, as when a driver is thrown against the steering wheel in an automobile collision, is a frequent mechanism resulting in cardiac contusion or rupture. Bright and Beck⁹⁹ analyzed 152 cases in which death was caused by rupture of the heart, as shown by autopsy. They conclude that an accurate differential diagnosis between cardiac contusion and coronary disease is almost impossible. On the other hand if a patient who has previously been in good health receives an injury and develops signs of circulatory embarrassment, he should be considered as having sustained cardiac injury. Treatment consists in absolute rest and sedation, mild laxatives to avoid straining and digitalis as necessary for irregularities. Rupture, if it is not an immediately fatal lesion at the time of injury, ordinarily occurs in the second week. Immediate operation is indicated, hence a thoracic surgeon should be readily available during this period. The authors suggest a pericardial graft at the suture line if the myocardium is infiltrated or extensively bruised or softened.

Crynes and Hunter¹⁰³ believe that the supposed rarity of traumatic rupture of the pericardium is not correct. They think that the scarcity of information concerning pericardial rupture is probably due to the fact that it is usually but one of multiple injuries terminating fatally and in itself may or may not contribute to the cause of death. They discuss a case in which was discovered an extensive pericardial rent, occurring in the absence of evidence of serious damage to the thoracic or abdominal viscera. The patient, a boy, lived for two and a half years after a crushing injury with but few symptoms attributable to the lesion present at autopsy.

Decker¹⁰⁴ raises the question whether foreign bodies in the heart and pericardium should be removed. He reviews 109 cases of foreign bodies in heart and pericardium reported since 1900, and states that foreign bodies should not be removed simply because of their presence. No emergency exists in those patients who survive the original trauma, unless one chooses to consider that free bodies in the pericardial cavity, sharp needlelike bodies and large objects need immediate or early surgery. Indications for removal must be based on prognosis and review of the condition of the patient and the degree and duration of the disability.

Turner¹⁰⁵ reports a case in which a bullet, with its base in the myocardium, protruded into the chamber of the left ventricle. When the heart was exposed at the time of the original injury, the bullet could not be seen or palpated and the attempt to remove it was reluctantly abandoned. The patient was well twenty-three years later.

Suppurative Pericarditis

Suppurative pericarditis is not a rare disease, but it must be suspected and sought in cases of generalized or thoracic infection if the diagnosis is to be made in a high percentage of cases. Strieder and Sandusky¹⁰⁶ reviewed 28 cases collected from the literature from January 1, 1934, to January 1, 1940, and added 10 cases from the Boston City Hospital, which brought the total of the recorded cases for which pericardiostomy had been performed to 265. The mortality for cases so treated is approximately 50 per cent. Without operation the mortality approaches 100 per cent. With the advent of chemotherapy the mortality with operation should be further reduced. When the diagnosis is made, operation should be undertaken forthwith. There is no reason for delay as there is in early empyema thoracis. It is unfortunate that some physicians are under the impression that chemotherapy together with pericardicentesis suffices to effect a cure in a large percentage of cases. If chemotherapy is of value as an adjunct, its effectiveness should be measurably increased by the prompt establishment of early, open, adequate pericardiostomy.

In cases with generalized infection, even with pericardiostomy, the prognosis remains that of the pre-existing infection, although, by relief of the cardiac tamponade, the operation may be a life-saving measure. Adams and Polderman¹⁰⁷ performed pericardiostomy on 3 patients with pneumococcal pericarditis, 1 of whom recovered. Of the 20 cases reported by these authors, 12 were secondary to pneumonitis or pneumonia, 6 to osteomyelitis, 1 to cholecystitis, and 1 to mastoiditis. In 5 patients with staphylococcal pericarditis an abscess was found in the heart muscle. The electrocardiogram may be of diagnostic aid in such patients. Malec and Midelfart¹⁰⁸ successfully performed pericardiostomy in a case of purulent pericarditis complicating streptococcal empyema. They advocate early adequate drainage and state that it rarely results in postoperative adhesive pericarditis, an opinion that is shared by Shipley.¹⁰⁹ In an operative experience with 8 cases, with 4 recoveries, I have not observed adhesive pericarditis as a late complication.

For purulent pericarditis the low anterior approach with the resection of the fourth and fifth left costal cartilages is probably the best, and is the one oftenest used. Donaldson¹¹⁰ has recently advocated a modification of the old Allingham approach for the drainage of nonpurulent effusions.

Constrictive Pericarditis

Since Churchill's¹¹¹ report in 1929 of the first successful resection of the pericardium for con-

strictive pericarditis in the United States, many other successes have been recorded, and the operation is now the accepted treatment in suitable cases of this disease. Blalock and Burwell¹¹² have published an important review of the subject, to which the reader is referred. In it they discuss 28 cases of constrictive pericarditis that they observed at the Vanderbilt Hospital in Nashville, Tennessee. The etiologic agent was established in 21 cases by aspiration, operation or autopsy, and was found to be the tubercle bacillus in 18 cases and *Staphylococcus aureus* in 3. Twenty patients had pericardectomy. Twelve were cured or greatly improved, whereas 8 died from several hours to two years after operation. These results are in accord with previous observations that approximately 60 per cent of the patients are either cured or greatly improved by the operation.

Harrington and Barnes¹¹³ discuss the diagnosis and surgical treatment of chronic constrictive pericarditis and report 9 cases. Three patients were cured, 3 were improved, and 3 died, the deaths occurring three, four and twenty-nine days, respectively, after operation. Heuer and Stewart¹¹⁴ have reported 7 operations without a death. Three of the patients were cured and 4 were markedly improved.

Tumors

Gebauer¹¹⁵ reports a case of a huge intrapericardial teratoma containing a large, probably infected dermoid cyst that he removed at operation from a twelve-year-old girl. The patient died of uncontrolled hemorrhage from the aorta, which was inadvertently injured.

Beck¹¹⁶ has successfully removed an intrapericardial teratoma. He also describes a case of a tumorlike mass in the wall of the left ventricle. The identity of the lesion was not established, but it was probably not a true neoplasm. This seems to be the first case in which a benign lesion of the heart has been recognized clinically and the only one in which removal of the lesion has been effected surgically. The patient was in good condition eighteen months after operation. Aneurysm of the left ventricle had not developed.

Angina Pectoris

Attempts to improve the blood supply to the ischemic heart by the establishment of a collateral circulation by surgical measures have continued. Unlike total thyroidectomy and alcohol injections about, or operations on, the sympathetic cord and rami of the upper thoracic region, which treat only the symptoms of angina, these attempts are based on physiologic principles and are directed at the underlying disease.

Beck¹¹⁷ was the first surgeon to apply these principles. His original operation consisted in grafting the pedicled pectoralis major muscle to the heart.

Schildt et al.,¹¹⁸ experimenting on dogs to produce new communications between the coronary arteries by the application of inflammatory agents to the surface of the heart, found that powdered asbestos was the most satisfactory substance. It reduced the mortality and the size of the infarct following ligation of a coronary artery. Recently, Beck¹¹⁹ has utilized this work and describes a new operation in which he abrades the parietal pericardium with special burrs and introduces powdered asbestos to further adhesions between the heart and mediastinal fat. He believes that fat is probably the best tissue for purposes of vascularization, but that all tissues that come in contact with the heart serve as grafts.

Feil¹²⁰ appraises the results in 37 patients with sclerosis of the coronary artery and angina pectoris operated on by the Beck technic. There were 14 postoperative deaths, a mortality rate of 38 per cent. Nine patients survived the operation but died four months to six years later. In 5 of these cases the results were excellent, and in 4 there was little or no improvement. Fourteen were still living, and of these, nine were definitely improved and 5 showed an increase in exercise tolerance and diminution in symptoms. The results in the 23 patients who survived the operation were as follows: excellent, 14 cases (61 per cent); good, 5 (22 per cent); little or no improvement, 4 (17 per cent).

O'Shaughnessy,¹²¹ of London, whose brilliant work was terminated by his death in Flanders before Dunkirk while serving with the British Army, used the omentum as a vascularizing agent in an attempt to increase the circulation to the heart. He reported his results in 20 cases. Fifteen of these patients were suffering from angina pectoris; 5 of these died and 8 of the remaining 10 were free of angina, 7 having returned to work.

Strieder and Clute¹²² have operated on two patients using the O'Shaughnessy technic. In one case there was an excellent result, but death occurred six months after operation as a result of an operation for diaphragmatic hernia, which was a complication of the original cardio-omentopexy. The second patient was still alive four years later, with only slight improvement in the angina but with a greatly increased exercise tolerance.

Thompson and Raisbeck¹²³ found that in animals adhesive pericarditis can be regularly produced by the introduction of sterile talc into the pericardial sac. Ligation of the descending ramus of the left coronary artery and vein at a point 1 cm. below the origin of this artery carried a mortality of 50 per cent. If this operation was repeated but in addition talc was introduced, the mortality was 25 per cent. In another group, talc was introduced and two or three weeks later a similar ligation of the artery was performed. In this group there were no deaths. Beck¹¹⁹ repeated these experiments but was unable to obtain the same bene-

ficial results as these authors report. Thompson and Raisbeck have, however, reported gratifying results in a group of patients incapacitated by their angina, who were completely or partially relieved of pain and were able to return to work.

I have introduced aleuronat paste into the pericardium of a woman who was completely incapacitated by angina pectoris. She is alive and doing her own housework four years later. Another patient, a man suffering from angina pectoris secondary to syphilitic aortitis, has been treated by introducing talc into the pericardium. At the time of operation he was unable to walk the length of the ward without precipitating an attack, but one year later he was able to walk four miles without pain. He died in cardiac failure one year after operation, and autopsy showed complete obliteration of the pericardial space with a rich collateral vascular system.

A somewhat different approach to this problem has been used by Fauteux,¹²⁴ who found that if he ligated the magna cordis vein of the dog's heart and ligated the descending ramus of the left coronary artery, the mortality was much less than if he ligated only the artery. The important practical result of this procedure was a rise in arterial pressure in the entire apical region of the heart, the area drained by the surgically occluded vein. Fauteux and Palmer¹²⁵ ligated the great cardiac vein in 6 patients. One, a man of fifty-four, was working as a janitor two years after the intervention. Five others survived the operation for shorter periods of time. All were relieved of pain.

There is no implication that ligation of a vein will prevent thrombosis in an atheromatous but patent coronary artery, but there is evidence that venous ligation will cause changes in the vascular bed, such that, if thrombosis does subsequently occur, infarcts may be limited in size if not actually prevented from forming.

This highly important and controversial subject is still in a state of flux, and much work remains to be done. Many more patients must be operated on and the results must be carefully appraised before significant conclusions can be drawn. Beck¹²⁶ best sums up the matter as follows:

Our interest should be focused on the point as to whether or not a reasonable quantity of blood can be made to pass from the grafts into the heart, regardless of the procedure and regardless of the tissue used . . . We have been able to demonstrate vessels between the grafts and the heart, however, we have no way of knowing how much blood went through these channels. If these channels are numerous enough and large enough to transport a reasonable quantity of blood, then the principle upon which the operation is based would be established. If the principle were satisfactorily established, then the best method for doing the operation would become important.

Intracardiac Surgery

Harken¹²⁷ believes that recent advances in thoracic surgery suggest that it is time to take up experi-

mental intracardiac surgery. Working in the surgical research laboratories of the Boston City Hospital, he has devised an ingenious method of producing bacterial endocarditis by attaching a metal clip to the posterior mitral leaflet. The clip is introduced through the left auricular appendage. Following the injury to the valve leaflet, the character of the endocarditis and the specific nature of the vegetations were directed by the administration of sulfanilamide derivatives and subsequent injection of the desired bacterial strains. Harken¹²⁸ has also devised a new cardioscope by means of which it is possible to visualize in the experimental animal the chambers of the heart, the valve leaflets, the clips in place and the chordae tendineae with moderate facility. It is entirely within the realm of speculation that some day cardioscopy will play an important part in surgery of the heart.

CASE 30371

PRESENTATION OF CASE

A thirty-three-year-old bartender was admitted to the hospital because of jaundice.

The patient was apparently well until about six weeks prior to admission, at which time he noted that he tired easily and lacked his usual vigor. His appetite became poor, and he had episodes of morning nausea and vomiting. He also developed muscle cramps in the legs, low backache and brief cramplike epigastric pains just to the left of the midline. Two and a half weeks before entry he was told that the whites of his eyes were becoming yellow, and this was followed in a few days by a noticeable yellowing of the skin, which continued to increase. There was no associated pruritus, and there was no history of chills or fever. The urine became dark, but the stools remained normal in color. Frequent doses of magnesium citrate were taken for constipation. A few days prior to entry he noticed that the abdomen was enlarging and felt firm. On the day of admission a small amount of bright-red blood was noted in the stools.

For the preceding ten years the patient had been a bartender and was in the habit of drinking about a pint of liquor, supplemented with ten to twelve glasses of beer or ale, daily. He often went without food for several days at a time, although consuming the usual amount of alcohol. He smoked heavily — two or three packages of cigarettes daily — but denied taking drugs. There was no history of intolerance to fatty foods, abdominal distress or previous attacks of jaundice. The patient had noticed occasional swelling of the ankles in recent months.

The family history revealed that his mother had been operated on for gallstones and that his father, also a heavy drinker, had been confined at a state hospital for several years.

Physical examination on admission revealed a well-developed rather obese man who was intensely jaundiced. The skin was lemon yellow rather than orange or bronze. A few small spider angiomas were present on the anterior chest and right upper arm. The palms of the hands were erythematous, especially at the periphery. The tongue was beefy

*On leave of absence.

red and slightly smooth. The heart and lungs were clear. The abdomen was moderately distended. The liver edge was tender and palpable a hand-breadth below the costal margin and also to the left of the midline. The knee and ankle jerks were absent, and there was hypoactivity of the deep tendon reflexes of the upper extremities. The calves were tender to pressure.

The temperature was 100.4°F., the pulse 88, and the respirations 24. The blood pressure was 100 systolic, 65 diastolic.

Examination of the blood revealed a red-cell count of 3,490,000, with 12.5 gm. of hemoglobin. The white-cell count was 11,700, with 85 per cent neutrophils. The urine had a specific gravity of 1.010 to 1.020, with negative to ++ tests for albumin and a ++++ test for bile. The sediment on one occasion revealed numerous bile-stained coarsely granular casts; no leucine or tyrosine crystals were seen. The urine urobilinogen varied from negative to positive in a 1:16 dilution. Although one clay-colored stool was seen on admission, subsequent specimens were brown, soft and formed, often with a positive guaiac test. The van den Bergh test was 8.0 mg. direct and 22.0 mg. indirect. The serum protein was 5.7 gm. per 100 cc., with an albumin-globulin ratio of 1.0. The cephalin-flocculation test was + in twenty-four and ++ in forty-eight hours. The alkaline phosphatase was 5.0 Bodansky units per 100 cc. The nonprotein nitrogen was 33 mg. per 100 cc., and the cholesterol 134 mg. The prothrombin time was 38 seconds (normal, 18 to 20 seconds). A blood Hinton test was negative.

Roentgenographic examination of the abdomen revealed no evidence of stones, but there was definite enlargement of the liver and spleen. The patient was treated with transfusions, dextrose and Amigen intravenously and vitamins and choline by mouth. He had one transfusion reaction. His temperature varied between 100 and 102°F., with morning remissions.

On the tenth hospital day the spleen was palpable, and in the following days the spleen became larger while the liver appeared to diminish in size and to become more tender. Definite ascites was demonstrable. The van den Bergh was now 12.4 mg. direct and 18.0 mg. indirect. The nonprotein nitrogen rose to 47 mg. per 100 cc., and the serum protein fell to 4.7 gm. The cephalin-flocculation test was + in twenty-four and ++ in forty-eight hours. The chloride was 86 milliequiv. per liter. The fasting blood sugar was 110 mg. per 100 cc. before and 117 mg. after the administration of 0.7 cc. of a 1:1000 adrenalin solution.

The patient continued to vomit and to complain of epigastric pain. Several stools contained gross blood, and on the sixteenth hospital day a clay-colored stool was noted. He became semicomatose and died on the nineteenth hospital day.

PATHOLOGICAL DISCUSSION

DR. BENJAMIN CASTLEMAN: The autopsy on this patient showed, as was expected, a good deal of ascitic fluid. The spleen was quite enlarged, weighing 450 gm. The liver presented an unusual appearance. It was large, weighing 3500 gm., which is about two and a half times the normal size, and was olive green and moderately firm; scattered throughout the organ were several small, finely nodular areas, averaging 1 to 3 mm. in diameter. The large size of the liver, plus the fact that it was green, made one believe that this was an obstructive cirrhosis. It had all the gross characteristics of obstructive cirrhosis or a biliary cirrhosis, except that the bile ducts were perfectly normal in caliber and there was no evidence of extrahepatic biliary obstruction. At the time of autopsy we toyed with the idea that this might have been one of the rare cases of intrahepatic cholangitic biliary cirrhosis. Microscopic examination, however, showed that the gross observations were incorrect, and that the diagnosis was alcoholic cirrhosis. Almost every other cell contained the characteristic alcoholic hyalin that is seen in the degenerated liver cells, and there was a fair amount of fat scattered throughout. There was early connective-tissue formation, but not the dense fibrous tissue that one sees in longstanding cirrhosis. In other words this is what has been called a "subacute alcoholic cirrhosis,"* a liver on its way to the chronic stage. Perhaps a year before it weighed about 5000 gm., was full of fat and had little, if any, connective tissue; at the time of death it was beginning to shrink. There was a great deal of necrosis in the liver cells, with polymorphonuclear and lymphocytic infiltration, which one could argue was either an acute hepatitis or a toxic manifestation from whatever produces alcoholic cirrhosis. In any event acute degeneration was still going on.

There were many purpuric spots throughout the lung and slight focal bronchopneumonia. The kidneys were tremendous in size, each weighing almost 400 gm., and microscopically showed a bile nephrosis. The heart weighed 400 gm. and was markedly dilated, which possibly was a manifestation of vitamin deficiency.

CASE 30372

PRESENTATION OF CASE

A sixty-nine-year-old Norwegian housewife was admitted to the hospital because of pain in the epigastrium.

As a result of the patient's poor memory the history obtained was rather inadequate. Fifteen years prior to admission she underwent an abdominal

operation but was unable to state what had been done. Since that time pressure sensations and pain in the epigastrium had become increasingly frequent after meals, especially after the ingestion of greasy foods, fruit and desserts. Nine months prior to entry she noted increasing tiredness, associated with dyspnea on exertion and orthopnea. On consulting a physician, she was told that she had heart disease, and she was treated with digitalis and bed rest on and off for a period of three months, with apparent improvement. Three weeks before admission she developed severe epigastric pain after eating liver. The pain persisted and interfered with sleep, and she became increasingly weak, so that hospitalization was advised. She had lost about 20 pounds over a period of two or three years.

Physical examination on admission revealed an emaciated woman with a sallow complexion. Bilateral lens opacities were present. The pulse was flatly irregular, and cardiac murmurs were audible. Palpation high in the left upper quadrant revealed tenderness and a fullness that suggested a mass.

The blood pressure was 135 systolic, 90 diastolic. The temperature was 99°F., the pulse 90, and the respirations 20.

Examination of the blood revealed 13.8 gm. of hemoglobin and a white-cell count of 15,600, with 84 per cent neutrophils. The urine had a specific gravity of 1.020 and gave a + test for albumin; the sediment contained 4 red cells, 6 white cells and many epithelial cells per high-power field. The blood nonprotein nitrogen and sugar were normal. The serum protein was 6.1 gm. per 100 cc., and the chloride 94 milliequiv. per liter. A Hinton test was negative.

A gastrointestinal series revealed no intrinsic esophageal gastric or duodenal lesion. A mass was visible in the midabdomen, medial to the body of the stomach and tending to displace it to the left. No adhesions between the stomach and the mass could be demonstrated.

On the fourteenth hospital day an operation was performed.

DIFFERENTIAL DIAGNOSIS

DR. CARROLL C. MILLER: The history and physical examination in this case are rather incomplete. We have no data that allow the pathology to be attributed to any one system of the body, except perhaps for two or three apparently minor details. The patient was an old woman who had apparently been going downhill for fifteen years, although the weight loss and indigestion were more marked during the two or three years prior to admission. It seems to me that we have to rule out certain conditions of the gastrointestinal and urinary tracts before going to the other systems and organs that might be involved. There was one x-ray study, a gastrointestinal series. May we see the films? I think that the description is clear enough in the record,

*Hall, E. M., and Morgan, W. A. Progressive alcoholic cirrhosis: clinical and pathological study of sixty-eight cases. *Arch. Path.* 27: 672-690, 1939.

DIFFERENTIAL DIAGNOSIS

DR. FRIEDRICH W. KLEMPERER: This is, in brief, the story of a thirty-three-year-old man who for ten years had lived on alcohol and inadequate food. Then, without obvious reason, he proceeded suddenly, within two months, from good health to a death due to dysfunction of the liver. Practically all the symptoms, physical signs and laboratory data can be explained by dysfunction of the liver and avitaminosis. He had a short prodromal period—three and a half weeks—of vague complaints. He then became increasingly jaundiced and constipated and the liver began to enlarge. We do not know whether the liver had been large before this episode. He had had swelling of the ankles for several months. This is hard to interpret. It may have been due to cirrhosis of the liver. It could, however, be adequately explained on the basis of avitaminosis and protein deficiency. We know that the serum protein was low. It may also have been on a cardiac basis, because a beri-beri heart is frequently seen in alcoholic addicts.

On admission he was intensely jaundiced and the skin was lemon yellow rather than orange or bronze. We know that the urine contained bile, and the lemon-yellow color is therefore explained by the combination of bilirubin jaundice and anemia. Spider angiomas are typical of liver disease. "The tongue was beefy red and slightly smooth." This represents evidence of niacin (nicotinic acid) deficiency. We also have evidence of thiamine deficiency, because he had absent knee and ankle jerks and hypoaactive deep tendon reflexes of the upper extremities. The anemia may have been on a deficiency basis or may have been caused by blood loss from the intestinal tract. This bleeding could be adequately explained by the prolonged prothrombin time, again a sign of dysfunction of the liver. The renal function was good, as judged by the specific gravity of 1.020. Slight albuminuria was present, as often occurs in cases with marked damage to the liver. Bile was excreted in the urine, and also a small amount of urobilinogen, which indicates that bile passed into the intestine. The van den Bergh test gave high values, particularly by the indirect method, which is usually taken as an indication of damage to the liver cells and is evidence against an obstructive jaundice. We have further laboratory evidence of liver dysfunction in the low serum protein, particularly the low albumin, the positive cephalin-flocculation test, the prolonged prothrombin time and the decreased cholesterol. The adrenalin-glucose test simply means that there was not enough glycogen in the liver to be broken down to give a significant rise in blood sugar.

From the time of admission the course was gradually downhill, and the patient died the usual death of liver insufficiency.

The cause of this man's liver deficiency was most probably a combination of avitaminosis, protein-deficiency and alcoholism. A primary infectious disease, such as Weil's disease, can safely be ruled out because of the long afebrile prodromal period and the absence of nephritis. We are told that the patient had not taken any drugs, so that a toxic hepatitis due to something other than alcohol can probably be ruled out. There is one other possibility that I do not believe can be ruled out clinically and certainly not pathologically; that is, the hypothetical virus that causes so-called "catarrhal jaundice" may be superimposed on liver damage already done by the alcoholism and in this way cause a rapid downhill course. We have some clinical evidence against it—the relative length of the prodromal period and the absence of leukopenia and lymphocytosis. Because I know that the pathologist cannot tell this kind of jaundice from toxic hepatitis, I feel safe in ruling it out.

The question remains, Did the patient have cirrhosis of the liver or subacute yellow atrophy, that is, degeneration of the parenchyma of the liver? The course to my mind is somewhat too rapid for cirrhosis of the liver. The absence of evidence of collateral circulation does not help in differentiating the two conditions, because it hardly would have developed within two months. Ascites was not a predominating symptom, except toward the end of the disease. I cannot rule out a cirrhosis of the liver that was asymptomatic previous to the terminal episode, but there is no evidence in the record to support this view. I believe that, as occasionally is seen in alcoholism, the patient died of parenchymatous degeneration of the liver with fatty degeneration. Two months are enough time to give rise to regeneration and fibrotic changes in the liver, so that cirrhosis or beginning cirrhosis may also have been seen at autopsy.

CLINICAL DIAGNOSES

Subacute yellow atrophy of liver, with hepatic failure.
Alcoholic cirrhosis, early.
Splenomegaly.
Ascites.

DR. KLEMPERER'S DIAGNOSIS

Toxic alcoholic hepatitis, with early cirrhosis.

ANATOMICAL DIAGNOSES

Subacute alcoholic cirrhosis of liver.
Ascites.
Jaundice.
Hemorrhages into lung parenchyma.
Bile nephrosis.
Bronchopneumonia.
Cardiac dilatation.

iller was not much smarter than we were. When this woman came in she was miserable, as well as rattling, as it states in the record. We thought she had a carcinoma of the pancreas. I did not want to operate, but the family doctor, who was younger than we were, thought she ought to be operated on. I doubted that we could do more than establish a diagnosis.

CLINICAL DIAGNOSIS

Carcinoma of pancreas.

DR. MILLER'S DIAGNOSIS

Pancreatic cyst?

Retroperitoneal malignant tumor?

Hepatoma?

ANATOMICAL DIAGNOSES

Cholelithiasis.

Chronic cholecystitis.

Choledocholithiasis.

Chronic passive congestion of liver.

Anomalous lobe of liver?

PATHOLOGICAL DISCUSSION

DR. McKITTRICK: At operation the mass proved to be a congested liver. In retrospect, we paid too little attention to the fibrillation and to the pos-

sibility that it might have led to cardiac decompensation and an enlarged liver, thus accounting for the mass; in other words, we "missed the boat." But that was not all. What she really had was a gall bladder full of stones and a common duct full of stones, which are what the family doctor suspected. So through a left-sided incision we took out the gall bladder and removed the stones from the common duct. Then, thanks to the help of Dr. Conger Williams of the Cardiac Department, her heart failure was properly treated and she was not much the worse for wear. Of course we were extremely anxious to get her well after we had learned that she did not have cancer of the pancreas.

DR. CASTLEMAN: The biopsy of the liver showed slight congestion, not severe failure, and I wonder if the mass was merely an anomalous lobe.

DR. McKITTRICK: As a matter of fact, the patient had clinical heart failure, but some of us did not recognize it.

DR. CASTLEMAN: The gall bladder showed marked inflammatory change.

DR. McKITTRICK: This case provides one good lesson: one has to be very careful about getting the mind centered on a particular thing. Dr. Miller and I both centered our minds on the mass.

but it will be interesting to see the exact location of the tumor mass.

DR. LAURENCE L. ROBBINS: I should be glad to talk about the tumor mass but I cannot see it; the statement in the record was probably based on an observation made during fluoroscopy. The body of the stomach is more to the left than usual, but I certainly cannot see anything that suggests a definite mass pressing against the stomach.

DR. MILLER: Was a pyelogram made?

DR. ROBBINS: No. I think that I can see the upper pole of the right kidney, which looks all right. This may be the left kidney. Since the films were not taken with that in mind, it is difficult to be sure about them.

DR. MILLER: Except for a possible connection with the stomach, an x-ray study such as this would probably be of significance only in localizing the tumor more accurately. Were any guaiac tests on the stools reported?

DR. BENJAMIN CASTLEMAN: No.

DR. MILLER: And no diastase or amylase tests?

DR. CASTLEMAN: No.

DR. MILLER: It seems to me that the discussion must come down in a rather vague way to two questions. What tumors occur in the left upper quadrant? What is the likeliest diagnosis in this particular case?

From the description of the x-ray films and the fluoroscopic examination, I suspect that the tumor was not in the splenic area. A kidney tumor, possibly a large cyst or a hypernephroma, may displace other viscera one way or another. The fact that there was no connection between the tumor and the stomach rules out fairly well a lesion in the stomach. The gall bladder is a curious organ in that it may, when enlarged, extend in a number of directions. Usually hydrops of the gall bladder extends downward and a mass may be found in the right lower quadrant, but it is unlikely to extend to the left in the region of the lesser curvature of the stomach. The retroperitoneal region must also be considered. The retroperitoneal tumors most generally found in this location are the fibrosarcomas and lymphomas. Then there are mesenteric cysts in the gastrohepatic and gastrocolic ligaments. Mesenteric cysts are most frequently found in young children and extremely rare in the sixty-nine-year-old range. The pancreas is the next likeliest, perhaps I should say the likeliest, location for a tumor that presents in the region of the lesser curvature of the stomach. Pancreatic cysts are fairly frequent and are usually not associated with any changes in blood chemistry, digestive processes or other physiologic reactions. They gradually increase in size, displace organs and finally become diagnosable either by palpation or because of pressure symptoms on adjacent organs.

Another diagnosis that is interesting to postulate is a tumor of the left lobe of the liver, such as a

hepatoma. I have seen one such case in which the hepatoma presented by x-ray as a solid mass in the left upper quadrant medial to the stomach.

Are there any data in the history that lead us to a diagnosis of any one of these conditions? The first symptoms were pressure and pain. Naturally with a tumor of increasing size there might have been a sense of pressure, particularly after eating. As the stomach became filled with food there were symptoms of indigestion, particularly after greasy foods, fruits and desserts, which are more poorly digested than other foods. This could have been due simply to pressure against normal peristalsis. The suggestion of greasy food makes one think of a disorder of the gall bladder, liver or pancreas, but I do not believe that we have enough evidence of disease in either of these organs to be incriminating except perhaps for the pancreas, as I have said.

The pressure and pain were experienced intermittently and progressively over a fairly long period of time — three weeks before she was admitted. What is it in tumors and cysts that causes trouble? If the cyst has a pedicle it may become twisted and thereby infarcted. Its enlargement may cause pain owing to stretching of the capsule, and if it enlarges so as to press on its own mesentery it will cause various changes incident to gangrene or infarction. Infection is also a frequent complication of cysts. This again causes swelling and infarction if the process goes on long enough. The other eventuality is the development of malignant degeneration.

The laboratory data provide no significant information. The patient had a temperature of 99°F — a bare elevation — and a white-cell count of 15,500, with 84 per cent neutrophils. This would go along with hemorrhage or with the early stages of infarction of a tumor. We do not know whether the urine was a catheter specimen. It gave a + test for albumin, and the sediment contained 4 red cells. If it was a catheter specimen, the presence of the red cells is important. A woman of this age may have senile vaginitis, with red cells in a voided specimen; if it was a catheter specimen, however, the red cells probably came from higher up. There is no other sign of involvement of the kidney, but the failure to take an intravenous pyelogram resulted in the missing of an opportunity to see a tumor. The blood sugar was normal. In pancreatic cysts there is often not enough damage to the pancreatic substance to produce a diabetic state or any change in the amylase or diastase level. The blood protein was normal, and the chloride slightly depressed.

My first diagnosis, a purely presumptive one, is pancreatic cyst. The next two possibilities, which are less likely, are a retroperitoneal solid tumor with malignant degeneration and a hepatoma.

DR. LELAND S. MCKITTRICK: I am not proud to carry on this discussion, and I am glad that Dr.

rhythm may result.^{9,10} The observations of Winkler, Hoff and Smith,¹¹ however, indicate that the chief objection to the use of potassium salts arises from their possible irritating effect on the upper gastrointestinal tract. This irritation is probably of significance when potassium chloride or iodide is used, but probably is less important when potassium bicarbonate, acetate or citrate is employed. The findings of these workers indicate that serious cardiac complications or fatal poisoning from the oral administration of potassium is a distinct possibility only when there is complete, or almost complete, anuria associated with a high degree of nitrogen retention. They state, "The relatively slow absorption, the vomiting when large doses are given, the mode of distribution in the body and, most important of all, the continued ability of the most severely damaged nephritic kidney to excrete potassium all combine to make such poisoning very difficult to bring about."

The use of potassium bicarbonate, or that of the acetate or citrate if either is readily available, thus offers a useful adjunct to sulfonamide therapy and is certainly worthy of extensive clinical trial. Until more information concerning toxicity becomes available, it seems advisable to use small doses (5 to 10 gm. daily) and to administer these substances with care to nephritic patients who show evidence of moderate or marked nitrogen retention.

QUALITY VERSUS QUANTITY PRODUCTION

THE Maternity Center Association of New York, in the June issue of its bimonthly broadside *Briefs*, points out the advances that have been made in reducing maternal and infant mortality, as well as some of the dangers that continue to exist. Despite the difficulties imposed by war conditions, with shortages of physicians and nurses and overcrowding of hospitals, the maternal mortality in the United States reached a record low level of 2.1 per 1000 live births in 1943. Infant mortality also achieved a new low point.

This success is attributed to the following factors: the profit derived from studies of the causes of maternal mortality; public education; advances in obstetric knowledge, with new, important life-saving discoveries; the increasing rate of hospitalization; the Social Security Act, with the Government entering the field of maternity and infancy care on a grand scale; and the Emergency Maternity and Infancy Care Plan for the wives of men in the four lowest pay grades of the armed services.

Dangers that still block our arrival at a millennium are listed as follows: the continued existence of many poorly managed and poorly equipped small hospitals in both urban and rural areas; the continued high death rate of infants under one day of age, due largely to prematurity and birth injury; continued outbreaks of infectious diarrhea of the newborn; and lack of positive good health and hygienic living conditions for so many of our expectant mothers.

From the expansion of this theme—the reduction in maternal and infant mortality—the broadside goes on to a somewhat ambiguous discussion of the political aspects of birth rates. In this discussion the usual failure to distinguish properly between quality and quantity production is found. All political leaders, mindful mainly of muscular competition between nations, have viewed declining birth rates with apprehension and have rightly feared dwindling populations while their aggressive neighbors bred huge potential armies. The *folie raisonnée* of the blustering nations that needed more

ALKALINIZATION DURING SULFONAMIDE THERAPY

A NUMBER of investigators¹⁻⁵ have recommended the routine use of alkalis, in the form of sodium bicarbonate orally or sodium lactate parenterally, as an adjuvant to sulfonamide therapy. They have presented evidence to indicate that this tends to prevent crystalluria and its concomitant damage of the urinary tract. Daily doses of 15 to 24 gm. (average, 20 gm.) of sodium bicarbonate or 1500 to 2000 cc. of one-sixth molar sodium lactate solution (27 to 36 gr. of sodium lactate) are usually required to maintain the alkalinity of the urine for this purpose. It is claimed that clinical experience with these drugs has resulted in almost complete

elimination of urinary-tract complications (crystalluria, hematuria, renal colic and anuria).

It is known, however, that the administration of such large doses of a sodium salt may, in certain types of patients, result in the retention of water in amounts that may be serious and even dangerous. This may be expected particularly in patients with cardiac, renal or hepatic insufficiency of even mild degree and often occurs in pregnant women. Indeed Lyons and his associates⁶ have shown that water retention may result in normal persons from the ingestion of similar amounts of sodium bicarbonate. These investigators gave 50 gm. of sodium bicarbonate to each of six normal subjects over a period of forty-eight hours. They found an average increase of 400 cc. in the plasma volume and an average increase of 1.6 kg. in body weight, an increase of 14.4 per cent in the former and one of 2.3 per cent in the latter. Slightly greater increases were found after the ingestion of 40 gm. of sodium chloride over a similar forty-eight-hour period. Edema due to water retention is also frequently observed postoperatively in patients receiving parenteral injections of sodium chloride solutions containing equivalent amounts of sodium. Furthermore, the recommended amounts of alkaline drugs have a tendency to increase excretion of the sulfonamide drugs, thus necessitating the use of larger doses of these drugs to maintain the desired blood concentration.⁷ Should this increased excretion occur in a patient who also had water retention, the renal complications might be increased rather than eliminated, in spite of the greater solubility of the excreted drug in the alkaline urine.

Elsewhere in this issue of the *Journal*, Drs. Ohnysty and Wolfson present evidence that these difficulties may be overcome by substituting potassium salts, particularly potassium bicarbonate, for sodium salts in alkalizing patients during sulfonamide therapy. The use of potassium bicarbonate has the advantage of producing the same alkalinity in the urine and at the same time having a diuretic effect,⁸ instead of the water-retaining tendency of sodium salts.

The use of potassium salts instead of the sodium salts has been rejected by previous workers because of the possibility that abnormal cardiac

THE PROBLEM OF POSTWAR SURGICAL TRAINING FOR RETURNING MEDICAL OFFICERS*

ALLEN O. WHIPPLE, M.D.†

NEW YORK CITY

THE subject of postwar training and rehabilitation of medical officers, now active in the Army, the Navy, the Marines and the Public Health Service in this country and on every continent and ocean, is closely linked with the plan and philosophy of the armed forces as they are functioning in this global war.

The experience of this country in the last war helping to win it but sharing an even greater responsibility in losing the peace was a sobering one. But the blind isolationists realized after the convincing evidences of the power and insane ambitions of Germany in Europe and the increasing encroachments of Japan in the Pacific that we were facing an inevitable conflict. But we were fortunate in having time to prepare for the war by getting our facilities mobilized during the early days of lend-lease, and the Nation was psychologically prepared for the draft and an all-out war effort before Pearl Harbor.

There was none of the flag-waving and impatient enthusiasm on the part of the citizenry and youth to enter this war that were evident in the last one. The young men and women faced the inevitable with a seriousness and a conviction that those of the World War I generation, not they, were responsible for the present situation in so deplorably losing the opportunities presented for winning the peace.

One of the outstanding differences between the conduct of the last war and the present one is the special training of the men in all branches of the service for their jobs. Because the armed forces were engaged in all parts of the world they have been given more careful selected training and more initiative than in the last war. The rapid development of fighting in the air, on the ground and on land under the ocean has produced weapons, machines and physical means of communication and

detection never conceived of in previous wars. This has resulted in the training and bringing out of initiative in literally millions of young people, male and female, that will demand expression, as soon as the war is over, in work and occupation that cannot be denied.

The last war, by and large, provided a type of experience in trench and stabilized warfare that was directly opposed to the later demands of civilian life. This war, because of its global distribution and its mobile character, is providing countless experiences that can be translated into success in civil life. Training programs and a more intelligent evaluation of previous experience, aptitudes and latent abilities have resulted in an incomparably more intelligent and efficient Army and Navy than we have ever had before, and a body of men and women who, because of this experience, will rightly demand a proper place in life on their return.

In a recent visit to our forces in Great Britain and North Africa I was impressed by the general concern of the soldiers and officers over four possibilities. First was the fear that war weariness and complacency at home would lead to a premature cessation of hostilities, — in which they were doing the fighting and dying, — which would again result in losing the peace. Second was a bitter resentment and anger over the conflict between capital and labor, resulting in strikes and interference with the war effort: the coal strike was threatening, and Lewis was more hated than Hitler. Third was apprehension regarding postwar opportunity and employment. Last was uncertainty regarding the utilization of their newly acquired experience and the means of further training to perfect themselves in these fields.

Just what will the answer be to this group of ten to thirteen million men and women as they return to civilian life? Do American businessmen, industrial leaders and professional groups believe that a World War I ideology and a Versailles Treaty attitude will be able to cope with this problem and provide leadership acceptable to these new veterans

*From the Department of Surgery, Columbia University.

†Valentine Mott Professor of Surgery, Columbia University, director, Resbyterian Hospital.

babies to make bigger armies to fight for more territory for their expanding populations is typical of the type of inspired leadership with which we have no sympathy, although we must fear it. To enter into direct competition with it is serving no useful future purpose.

A declining population is no more undesirable than a rapidly increasing one—both lead eventually to race suicide, the one by stagnation or inundation and the other by mass starvation or total war, or both. A high fertility rate and large populations in themselves, moreover, are no guarantee against military exploitation by one's aggressive neighbors, as witness the plight of China and India.

The only reasonable answer is the more effective use of that intracranial organ by which man is supposed to be distinguished from the lower animals, for the control of population growths and selective breeding. When we use half the ingenuity in the breeding and feeding of man that we now direct toward the science of animal husbandry, we may find that brave new world in sight.

MASSACHUSETTS MEDICAL SOCIETY

Medical societies in Kansas, Missouri and New Hampshire recently approved the establishment of nonprofit plans for the voluntary prepayment of medical and surgical bills resulting from hospitalized illnesses, injury and maternity care. This brings to eleven the number of states in which medical prepayment plans are co-ordinated with Blue Cross hospital-service plans. States in which medical plans were previously established and co-ordinated with Blue Cross plans are California, Colorado, Michigan, North Carolina, Delaware, Pennsylvania, Massachusetts and New York.

Of the above plans, by far the largest is Michigan Medical Service, sponsored by the Michigan State Medical Society. From recent reports one person in nine in Michigan is covered by this medical-care insurance, and during the four years of its life, Michigan Medical Service has paid to physicians in the state more than \$6,000,000.

The Michigan plan is beginning to prove that the profession itself can solve the health problems facing the nation and that physicians operating under the present free system have something

tangible to offer as a substitute for governmental medicine. Here in Massachusetts we have the same opportunity to solve the problem of a better distribution of medical care among the lower income groups and to forestall compulsory health programs but only if all the physicians in the Commonwealth give their enthusiastic and united support to the Blue Shield plan.

Doctors who have not yet become participating physicians are urged to communicate with the Blue Shield regarding participation in the plan. Doctors who have already become Blue Shield participating physicians are urgently requested to spread the gospel of Blue Shield protection among their patients and to distribute literature regarding the plan in their waiting rooms.

It seems unnecessary to add that the physicians who participate in the Blue Shield will be better off financially than they would be out of the plan. Figures are not available to show how much of the \$6,000,000 of disbursements by the Michigan Medical Service would have been collected by the doctors themselves, but if it is true that only 80 per cent collections are made by the profession, then the Michigan physicians would have received only \$4,800,000 for the amount of services.

The time to make an impressive record of achievement is now. When the war ends, and thousands of medical officers return to civilian ranks after witnessing the impressive and efficient distribution of governmental medicine to the 12,000,000 Americans in the armed forces, it may be too late. Furthermore, the 12,000,000 recipients of this same kind of medical care will undoubtedly have a good deal to say in the matter, but only if the Blue Shield has failed in its attempt to solve the problem.

In a recent survey in California, several interesting facts were established. Some of them are as follows: 88 per cent of the people think that the majority of doctors are doing a good job for the people; 34 per cent are against federal medicine; 50 per cent are in favor of federal medicine, and 16 per cent have not made up their minds. The question is, Why is there such a demand for federal medicine when there is such a high approval of the profession? The answer is, People believe that the cost of scientific medicine is too high. The conclusion is obvious. When something is needed by all the people but is too costly for them, eventually it is socialized so that it becomes available to all.

DEATH

JONES — Lombard C. Jones, M.D., of Falmouth, died August 17. He was in his seventy-ninth year.

Dr. Jones received his degree from Harvard Medical School in 1892. He was a member of the American Medical Association and the Harvard board of overseers.

His widow, a son, two step-daughters, two sisters and a brother survive.

(Notices on page xix)

to obtain surgical training in our well-equipped and adequately staffed hospitals after the war will be far greater than ever before. This will only complicate our own difficulties in providing proper facilities for medical officers seeking further surgical experience.

Out of all this complicated and difficult problem there may develop a clearer and more definite realization on the part of the medical profession and the laity that surgery, as a branch of therapy in the science of medicine, should be limited to those having adequate resident training, responsibility and experience. There is an increasing recognition of the importance of such training, as shown by the insistence of hospital boards that appointments to their surgical staffs be made from surgeons adequately trained and qualified by the boards of the several specialties.

The mortality and morbidity rates of the patients of properly qualified surgeons as compared with those of the casual operator engaged in general practice are so obvious to intelligent boards of management that they are insisting on limiting the surgery in their hospitals to qualified surgeons. The high standards of wound healing, preoperative and post-operative care and follow-up results that one finds in a well-trained surgical resident on a three-to-five-year program in teaching hospitals are so far superior to the oldtime self-made amphitheater and circus-performing surgeon that there is no comparison between them. One of the tragedies of this war is the interruption of the well-established program of resident training in so many of the hospitals of this country. It should be our aim and determination to restore this program as soon as the exigencies of war permit.

EPIDEMIC TYPHUS FEVER AND OTHER RICKETTSIAL DISEASES OF MILITARY IMPORTANCE*

C. S. STEPHENSON, M.D., D.S.C. (hon.)†

WASHINGTON, D. C.

THE rickettsial diseases of military importance are epidemic typhus fever, tsutsugamushi fever, trench fever, murine typhus fever and Rocky Mountain spotted fever. Although only a few cases of murine typhus fever have occurred in the military personnel during this war, some of them have occurred under circumstances that raised epidemiologic questions that had to be answered. The Rocky Mountain spotted fever group is at this time of least importance, since there is no large body of troops stationed in the endemic area.

Trench fever has been classified as a rickettsial disease and is louse borne. Organisms of the rickettsial group have been reported as recovered from lice and their feces fed on patients ill of trench fever. These organisms have subsequently infected volunteers. Trench fever disappeared following World War I before it was possible adequately to study the disease. It is again reported in Europe, however, and if future military operations require prolonged trench warfare it may recur there. Owing to the efficiency of the newer methods of louse control it should not produce the damage it caused in the last war.

With the exception of Q fever and trench fever, this group of diseases produces in the serums of patients agglutinins for the X strain of the proteus

bacillus — *Proteus vulgaris*. There is no known strain of proteus bacillus that agglutinates with Q-fever serums, and nothing has been reported concerning agglutinins in trench fever. The Weil-Felix reaction — agglutination of the proteus-bacillus group — is used to differentiate typhus fever, Rocky Mountain spotted fever, tsutsugamushi fever and other febrile exanthematous diseases. The serums of patients suffering from spotted fever and typhus fever agglutinate with OX19 and OX2 strains, whereas the serums of patients with tsutsugamushi fever agglutinate the OXK strain.

EPIDEMIC TYPHUS FEVER

The synonyms of epidemic typhus fever are as follows: shipboard fever, jail fever, putrid fever, petechial fever, typhus exanthematicus, *Fleckfieber* (German), *typhus exanthématique* (French), *el tabardillo* (Spanish) and *typho-esantematico* (Italian). It may be defined as an acute infectious disease caused by *Rickettsia prowazki*. In the majority of cases the onset is abrupt and is accompanied by a fever lasting about fourteen days, usually followed by a critical fall or in some cases by a rapid lysis of temperature. A striking feature of this disease is a "rose-spot" eruption that appears from the fifth to the sixth day of the disease, usually on the abdomen or loins and extending over the trunk and extremities. Under pressure the rash fades, radiating in a stellate form from the middle of the rose-red macule or papule. Other prominent features of the disease are profound stupor

of World War II? If so, we may be sure of a fusion of these millions of men and women and their families, resentful of such an attitude and ready to follow radical leadership into the most powerful pressure group this country has ever known, with a block of votes that will make any Congress dance to any tune.

What has been said about the men in the service in general applies equally to the medical officers in the armed forces. But they have additional problems peculiar to their profession. The older group have left practices of various kinds of work and compensation. Regardless of the efforts of their associates in their communities, not in military service, to preserve the work of these men, they realize that on their return to their homes they will have to salvage the greater part of their lost practices. The younger group, called to service before completing their residencies and with only short-term internships, have a common query: How and where can I complete my training? Many of these men, as well as those of the older group, have had to do varying amounts and kinds of war surgery, realize their lack of training and are anxious to get a more adequate experience in civilian surgery. A recent analysis of a pilot questionnaire sent to surgical officers in the Army shows that 77 per cent of the men graduating from medical schools between the years 1936 and 1942 desire further training as surgical residents.

A recent address by Surgeon General Kirk paid unstinted praise to the surgeons in the war zones and in military hospitals in reducing the mortality in casualties to a record 3.5 per cent, and stated that this was due to the selection of surgeons with adequate resident training and from those qualified by the several qualifying boards. Unfortunately, the accelerated medical curriculum and the limitation of postgraduate training to a nine-month internship and a limited number of men in the 9-9-9 plan — a program followed at the insistence of the Army and Navy for military reasons — have effectively stopped the supply and the training of the very group of surgeons who have been responsible for the high standard of service and accomplishment referred to by the Surgeon General. This is indeed a serious situation if the war continues for more than a year, for poorly educated and inadequately trained surgeons will be sent to do the most difficult kind of traumatic surgery. The goose laying the golden eggs is being killed.

This question of how to provide postwar training in surgery for men returning from military service is being discussed by many national medical and surgical organizations. Questionnaires are being sent to all the medical officers here and abroad by the American Medical Association and the American College of Surgeons. There is danger of too many cooks' spoiling this particular broth. The subject is being discussed in Washington,

in and out of Congress, but beyond providing for financial aid to the returning medical officer for periods equal to his time in the service, no concrete ideas have thus far appeared in Washington.

It is obvious that the many veterans' hospitals, already built and planned, to provide several hundred thousand beds for returning casualties, must be staffed. How to obtain qualified surgeons for these hospitals is one of the postwar problems that is not a congenial or promising topic in Washington. The Clark bill in Congress, not yet reported out of committee, provides, among other things, that the postwar training of medical officers shall be under the Veterans Bureau. The purpose of this bill is obvious. But how adequate will these veterans' hospitals be for such training? This will depend on their location, their proximity to medical teaching institutions and their relations with them and on the ability and experience and compensation of the surgeons and physicians appointed to the staffs of these hospitals. Unless the selection and appointment of the staffs of these hospitals are of an entirely different character from those of the last war, the postwar training of returning medical officers in veterans' hospitals will be a tragedy.

In the questionnaire referred to only 11 per cent of those replying indicated a desire to remain in governmental service, and a smaller percentage desired to work in veterans' hospitals.

In decelerating the medical-school curricula on the basis of the original four-year plan, which is being proposed beginning in 1945, there will be in the following three years a period of nine months to one year when there are no medical students available for internships. This may be of great help in providing places for medical officers, demobilized on a staggered program, to get further hospital training. But it will require the intelligent, patriotic and far-seeing co-operation of the medical boards and boards of managers of the better hospitals all over this country to rearrange the intern and resident training program to provide positions and opportunities for such training. The normal standards of surgical service have been badly compromised, and the ability of hospitals seemingly to function under war conditions with limited and poorly trained assistants will require a re-education of boards of managers to provide room and opportunity for these medical officers returning and desiring further training.

Undoubtedly most of the hospitals will give first choice and priority to the men who as interns or first-year and second-year residents left these hospitals for military service. But in addition a limited provision should be made in all these hospitals for men of demonstrated ability as medical officers to get further resident experience.

It must be realized that with the complete disorganization of medical centers and hospitals in Europe, the pressure from that and other continents

obtain surgical training in our well-equipped and adequately staffed hospitals after the war will be greater than ever before. This will only complicate our own difficulties in providing proper facilities for medical officers seeking further surgical experience.

Out of all this complicated and difficult problem there may develop a clearer and more definite specialization on the part of the medical profession and the laity that surgery, as a branch of therapy in the science of medicine, should be limited to those having adequate resident training, responsibility and experience. There is an increasing recognition of the importance of such training, as shown by the insistence of hospital boards that appointments to their surgical staffs be made from surgeons adequately trained and qualified by the boards of the several specialties.

The mortality and morbidity rates of the patients of properly qualified surgeons as compared with those of the casual operator engaged in general practice are so obvious to intelligent boards of management that they are insisting on limiting the surgery in their hospitals to qualified surgeons. and deafness, which may continue for months after the patient is well.

Epidemic typhus fever has probably killed more persons during periods of wars and famine than has any other disease. Medical history is indebted to Fracastorius for describing the first epidemic of typhus fever that can be readily recognized as such, as well as subsequent epidemics occurring in Italy from 1505 to 1530. Hirsch wrote of typhus fever as follows:

The history of typhus is written in those dark pages of the world's story which tell of the grievous visitations of mankind by war, famine and misery of every kind. In every age, as far back as the historical inquirer can follow the disease at all, typhus is met with in association with the saddest misfortunes of the populace; and it is, therefore, a well-grounded surmise that the numerous pestilences of war and famine in ancient times and in the Middle Ages, which are known to us . . . had included typhus fever as a prominent figure among them.

The scientific epidemiology of typhus fever began in the early part of the sixteenth century. It was rife over the greater part of Italy from 1505 to 1530. Soon thereafter numerous epidemics were reported from almost all the European states. The political and social disturbances of the seventeenth and eighteenth centuries and the first thirty years of the nineteenth served to spread repeated epidemics to all parts of Europe.

The epidemiologic records of the eighteenth century reveal that there was scarcely a year in that period in which great or small typhus-fever epidemics did not occur. In brief there are four periods of special importance. The first period began about 1690 and ended about 1720. Austria, Germany and Hungary were particularly involved, and Ireland had three severe epidemics, the two last having spread to England and Scotland. The years 1734-1744 comprise the second period, when Central and Eastern Europe were involved. It was a war pestilence in company with typhoid fever and the dysenteries. It is noteworthy that of all the great wars of which there is record, the American Civil War and the Franco-Prussian War in 1870 are the only ones in which epidemic typhus fever did not have a prominent place. The Seven Years' War and the war between England and Spain ushered in the third period (1757-1775). A severe famine occurred in Europe at that time and produced conditions favorable for the disease to spread. The revolutionary wars in France started the fourth period, which was by far the severest epidemic period of typhus fever in the eighteenth century. This period began about 1790 and lasted until the conclusion of peace in 1815. During that time typhus fever spread all over Europe. It was severest in the war-ravaged countries, but did not spare populations remotely removed from military concentrations or the travel routes of troops.

The Western Hemisphere had its first experience with epidemic typhus fever in Mexico, following the Spanish Conquest, where it became epidemic

in 1530. Pizarro began the conquest of Peru in 1526, and typhus fever soon appeared in the high lands of South and Central America, where it remains as an endemic disease known as *tobardillo*. Canada's first experience with the disease appears to have been in 1659, with several recurrences in the eighteenth and nineteenth centuries. The first great wave of Irish immigration to Canada was in 1847, the immigration and quarantine records showing that 84,445 persons immigrated to Canada that year. Of this number 75,540 came from Ireland. Among these, 30,265 persons contracted typhus fever. Of this number, 5293 died during the various voyages at sea, 8012 at Quebec and 7000 at Montreal—a total of 20,305 deaths. Several times during the eighteenth and nineteenth centuries typhus fever appeared in the seaports of the United States. Philadelphia had its last reported epidemic in 1883 and New York in 1893. Flippin in 1931 reported that 27 cases of epidemic typhus fever had occurred in Philadelphia since 1911. For some unaccountable reason louse-borne typhus fever has never established an endemic focus in either Canada or the United States.

The important endemic foci of typhus fever at the present time are China, Russia, Turkey, Syria, Iran, Irak, Arabia, Afghanistan, Spain, parts of France, eastern Europe, Germany, Italy, North Africa, parts of Central Africa and the mountainous sections of Central and South America.

Early in the present war, typhus fever began to increase in certain parts of Europe, North Africa and the Middle East. In 1942 the reported increase became so important that several conferences between representatives of the Army, Navy and United States Public Health Service were called and in the fall of that year the United States of America Typhus Commission was established by executive order of the President.

The most important epidemiologic features of epidemic typhus fever are as follows: It spreads rapidly among distressed populations disorganized by famine or war. It usually appears first in concentration camps, prisons and slums. It is a disease of cold weather; Hirsch analyzed one hundred and forty-seven epidemics and reported that thirty reached their peak in spring, twenty-eight in winter and spring, eighteen in autumn, seventeen in summer and fourteen in autumn and winter. It is associated with a louse-ridden population, and is readily transmitted from person to person by the body louse. An attack usually confers a long immunity; some investigators believe that the severer is the attack the longer is the immunity.

Epidemic typhus fever is transmitted by the louse *Pediculus humanus*. Nicolle, Conte and Conseil in 1909 proved by experiment that the chimpanzee could be infected with the disease by the injection of a small amount of blood from a human case in the active stage of the disease. They then infected

onkeys and proved that it could be transmitted from monkey to monkey by bites of the infected body use (*Ped. humanus* var. *corporis*). This work was confirmed in the United States in 1910 by Ricketts and Wilder. From the work of Goldberger and Anderson it seems clear that the head louse (*Ped. humanus* var. *capitis*) may transmit the disease under experimental conditions. It is not, however, regarded as an important vector.

Hume reports that the physicians in Serbia in the last war recognized the louse as the vector but believed that there were other methods of infection, especially favoring the inhalation theory. It was shown in 1923 by Arkwright and Bacot that rickettsias could survive in the feces of infected lice at room temperature for eleven days. The high mortality rate among physicians, nurses and orderlies in typhus-fever epidemics — especially since this group of persons is nearly always surrounded by many precautions against lice — strongly suggests that actual contact with lice is not always necessary. Since rickettsias are known to remain viable and to retain their virulence for at least eleven days in dried feces of lice, since experimental animals have been infected by intranasal inoculation, and since laboratory workers and others have contracted typhus fever in an unexplained manner, it seems highly probable that the inhalation of rickettsias in dried feces of lice has been responsible in some cases.

The most frequently reported period of incubation is eight to twelve days, but the period varies from five to fifteen days. The onset may be accompanied by a chill, usually not severe, which may be preceded by a few days of malaise, nausea, severe headache and loss of appetite. The fever usually reaches its maximum by the end of the first week. Morning remissions of fever are frequently seen, but are usually not very marked in the second week, by the end of which time the temperature usually falls by a rapid lysis, except that in complicated cases the patient does not become afebrile until the sixteenth day.

One of the most difficult symptoms to control is severe headache. Cardiac weakness and profound prostration may be seen from the very onset of the illness, and are usually most prominent in the second week. Constipation is a frequent and troublesome feature. The teeth are covered with sordes, which requires strict nursing care to control. Otitis media and parotitis are connected with this condition. The conjunctivas are injected. All the symptoms, especially the cardiac ones, may become exaggerated on the appearance of the rash. Nose-bleed may occur.

Mental disturbance is usually seen by the end of the first week and may vary from confusion, disorientation and restlessness to terrifying hallucinations that sometimes end in the patient's jumping from a window. Some of these symptoms

may remain in varying degrees of severity for weeks or months after the acute illness is over. Owing to the circulatory disturbance, gangrene, especially of the toes and less frequently of the fingers, is sometimes seen. It is often bilateral.

In uncomplicated cases with recovery there is a dramatic change in the condition at about the fourteenth day. The temperature falls and the mental condition greatly improves. In older patients the prostration and cardiac weakness may remain for a considerable period of time. As a rule younger patients make a more rapid recovery. Sequelae are rarely seen.

Cough is extremely frequent and may appear from the beginning of the illness, but is usually most annoying on the appearance of the rash. By the beginning of the second week the cough usually becomes less troublesome and various rales may be heard. Death from bronchopneumonia is frequent. Physicians in the Middle East report an unusual number of cases of bronchopneumonia in the present epidemic. Several physicians with extensive experience in this epidemic believe that some degree of bronchopneumonia is always present. They point out that in previous epidemics there was such a shortage of physicians that careful physical examinations were frequently impossible.

The eruption appears usually around the fourth day about the flanks and axillas and spreads to the chest and back. It is usually more pronounced on the back. It is seldom seen on the face, but is seen in the palms and on the soles. The rash lasts a varying time — from a few days to weeks. Occasionally markedly hemorrhagic rashes are accompanied by hematuria, hematemesis and melena which indicate a poor prognosis. The rash at onset easily disappears on pressure, leaving stellate radiations. Later it does not disappear so easily on pressure and becomes petechial.

A prominent feature is cardiac weakness due to myocardial damage. The heart sounds are weak, with a rapid, irregular pulse. The blood pressure is often quite low. Bradycardia is frequently seen in convalescence.

There is no characteristic blood finding. Leukopenia may be present in the first few days, but in uncomplicated cases the white-cell count rises to 10,000 or 15,000.

Albuminuria may be present from the onset, but disappears with convalescence.

Diagnosis

The most important laboratory finding is a positive Weil-Felix reaction during the second week of the disease. It reaches its height during convalescence and may rapidly disappear. For diagnostic purposes a test should be made in all suspected cases and repeated late in the second week. With a good antigen the serums of patients ill of typhus fever frequently reach titers of 1:10,000 to

1:100,000. The OX19 strain of the proteus bacillus is most frequently used, because it is more frequently agglutinated than is OX2. This reaction has no practical value in differentiating Rocky Mountain spotted fever from typhus fever. There are diseases not caused by the rickettsias that may show a titer in dilutions of 1:320 and occasionally higher.

An important recent advance is the utilization of the complement-fixation test in the diagnosis of typhus. In this test rickettsias of epidemic typhus fever are used as an antigen. The test becomes positive in the second week and may remain positive for the life of the patient.

On gross examination little is seen at autopsy except the fading rash, the complicating bronchopneumonia and splenic enlargement. Fraenkel in 1914 described the essential lesion as distinguished by injury to the capillary and precapillary vessels, characterized by proliferative changes in the endothelium of the arterioles and arterial capillaries, followed by necrotic changes, chiefly in the vessels of the skin, myocardium and central nervous system. There is a perivascular infiltration of small round cells. The lesions, which are microscopic in size, are most frequent in the skin, heart, great vessels, adrenal glands, testes, kidneys and brain, with the cerebral cortex usually the most involved part. Quite characteristic are the small paracapillary nodes of microglia. Plasma-cell infiltration and frequent thrombi have been reported. Splenic hemorrhages are frequently seen.

No specific treatment has proved of value. Many of the more recent chemotherapeutic agents have been used, with little success; in several cases there was evidence of harm from them. Convalescent human serums and serums from horses inoculated with rickettsias have been tried, with little benefit. A hyperimmune rabbit serum has been used in a small series of cases, with indications that it is valuable.

For the relief of the headache, acetylsalicylic acid is frequently not enough and resort to codeine or morphine is necessary. Constipation should be controlled, preferably with mild laxatives or enemas. Digitalis is of value in cases showing cardiac failure. Cardiac depressants are to be avoided. Every precaution should be taken to conserve the patient's strength. Good nursing is essential to prevent bedsores. In severe cases, particularly in elderly persons, the patient should be confined to bed until convalescence is well advanced.

This disease can be controlled by the destruction of lice. In a campaign against epidemic typhus fever, measures should be taken to include all persons in infected districts. This can only be done by house-to-house inspection, with removal of patients to hospitals and disinfection of all contacts, their clothing and houses. A quarantine should be established and all persons coming from

typhus-infected areas should be treated as contacts. Clothing and bedding can be disinfested either by heat or by chemical means, that is, by the use of louse powders. A recent popular article reports that 1,300,000 persons were deloused in Naples in January of this year and that one application of the powder to the clothing was effective for about six weeks.

The body louse nests in the seams of clothing and the louse-infested person should be bathed and the hair of the body and head should be clipped. In female patients great resistance to clipping is frequently encountered. Where this resistance is based on social customs or religious beliefs, it is far better to resort to oil and chemicals to kill the lice than to come in conflict with folkways. The new powders effectively solve the problem.

Physicians, nurses and orderlies in hospitals caring for typhus-fever patients should be provided with closely woven white-cotton, louse-proof garments fashioned like coveralls and open at the neck, wrists and ankles. Socks should be pulled over the bottoms and rubber gloves used on the wrists, and the neckband should be tightly closed. Because of the probability that infection has occurred from the inhalation of dried feces of lice, great care should be exercised in examining patients and in handling their bedding and clothing.

Several types of vaccine have been prepared for immunizing against typhus fever. Attenuated living rickettsias by heat or other means have been employed, but the inherent danger of using vaccines of these rickettsias has been shown by the fact that typhus fever has been produced by some of them. Rickettsias killed by phenol or formaldehyde are also used. The Weigl vaccine is reported to give good immunity, but it cannot be produced in large quantities. It is made by the injection of a suspension of rickettsias into the rectums of lice, which are subsequently fed to typhus fever-immune persons, after which the lower intestines are removed and prepared as a suspension that is used as a vaccine. About 200 lice are required to prepare a vaccine for one person. Vaccines made from killed rickettsias from the lungs of intranasally infected rats, mice or rabbits have been used.

The vaccine in use by the United States armed forces is the modified Cox vaccine, which is made from killed rickettsias from the developing yolk sac of the chick embryo. This vaccine gives good results in laboratory animals, but lacks adequate field tests in human beings. Typhus fever has occurred in a number of laboratory workers and in about 50 members of the armed forces, all of whom have been vaccinated, but there have been no deaths. It is the consensus that this vaccine has greatly modified the course of the disease in those who have acquired typhus fever subsequent to vaccination. It is used in a series of three inoculations.

ons, with a booster dose every few months when typhus-fever area.

ENDEMIC TYPHUS FEVER

The synonyms of endemic typhus fever are: rine typhus fever, Brill's disease and Mexican hus fever (*Tabardillo*). The causative agent been named *R. mooseri*. Brill in 1898 described orm of febrile disease of unknown origin that embled typhoid fever but gave a negative Widal ction. He noted that epidemiology of the disease ured from epidemic typhus fever in that it urred sporadically in a louse-free population and ; milder in character than the latter and had a erent seasonal occurrence. These facts caused him suspect some other vector than the louse as possible.

Maxey's work in the southern United States closed that most of the cases occurred among d handlers. This caused him to conclude that e reservoir in nature is the common rat. It seems ely that other rodents are also responsible.

Zinsser studied the records of 538 cases of Brill's eadise that occurred in Boston and New York ty between 1910 and 1933. Of these, about per cent occurred in foreign-born persons who d migrated from Russia. Ninety-seven per cent all the cases from 1910 to 1920 were in Jews, d over 80 per cent of the patients came from ussia. Zinsser believed that the cases of Brill's eadise represented recrudescences of infections quired in Europe.

Endemic typhus fever has occurred in all the utheastern states and as far north on the East ast as Boston, in the coastal cities on the West ast and in Texas. In 1929 the human cases ere largely limited to towns and cities. Nashville, ennessee, had about 75 cases in 1941. There e additional foci in Cincinnati and Cleveland, io.

Since endemic typhus fever became well known the United States it has been found in many parts the world, especially in coastal cities. It is known o exist in Australia, the Philippines, China, Indo-hina, Manchukuo, Malaya, Syria, Lebanon, Pal-stine, Egypt, Greece and southern Europe. In frica it was believed that many cases of endemic yphus fever were diagnosed as epidemic; however, ll the strains isolated by the United States of merica Typhus Commission are of the endemic ype.

The epidemiologic aspects of the disease are as ollows. The peak of prevalence is in the late sum-ner and fall. In the United States the disease as occurred most frequently among workers in ood-handling establishments. The literature re-ords that human cases are associated with rat arborages. (I saw 6 cases in Australia in September,

1943, in which connection with rats, mice or fleas seemed highly improbable.) The disease is not con-fined to slums. Transmission from person to person by contact with rat fleas has not been proved.

Except for the milder course of the disease the clinical features are identical with those of epi-demic typhus fever. The rash does not usually appear before the fifth day, and except in severe cases is not so extensive as in epidemic typhus fever. In mild cases only a few macules appear, and they may disappear in a few days. The general symptoms are milder.

The mortality rate in the United States is below 5 per cent, and most of the deaths occur in persons over forty-five years of age. In the Middle East, physicians believe that a careful compilation of statistics would reveal a higher fatality rate. This may be explained by the present food conditions. The general food supply is well below that of normal times, whereas in the United States the experience with murine typhus fever has been confined to a population not under stress of war and not living on such restricted subsistence levels.

This disease has frequently been confused with drug rashes, typhoid fever and meningococcemia. A diagnosis cannot be made until the rash appears. In localities where epidemic typhus fever, Rocky Mountain spotted fever and tsutsugamushi disease occur the diagnosis must be established by labo-ratory methods. The Weil-Felix reaction is positive in high titers.

In the light of the present knowledge the control of endemic typhus fever rests on the control of the rat population. The case against the rat is sufficiently strong, because of other diseases and economic considerations, to cause the medical pro-fession to increase the fight against it. It has been estimated that the rat population in the United States is in excess of 250,000,000. In the opinion of competent mammalogists this estimate is too low. They believe that each rat consumes \$2 worth of food and damages \$20 worth of food a year. This economic waste runs into billions of dollars and is entirely unjustified in peacetime; in war-time with world-wide food rationing it is intolerable. Bubonic plague has recurred in Palestine, and if it should be introduced into one of our eastern seaports it would be necessary to destroy rats on board ships sailing from a foul to a clean port. This would seriously interfere with wartime ship-ping.

It is extremely interesting to note that medical men have been slow to employ trained mammal-ologists in the fight against rats, yet they have extensively employed entomologists in the control of disease-bearing mosquitoes.

Vaccines have been prepared from the rickettsias of endemic typhus by the same technics as for epidemic typhus fever. They show good protection

in laboratory animals, but there is no adequate experience with them in human populations.

TSUTSUGAMUSHI FEVER

The synonyms for tsutsugamushi disease are kedani mite disease, Japanese river fever and mite (scrub) typhus fever. Until the advent of World War II the American literature has been singularly lacking in reference to this disease.

Japanese physicians claim that the disease has been recorded for more than a thousand years. The first clinical report was published by Palm in 1878. Hayashi first named the organism causing this disease in Japan, *R. tsutsugamushi*. Kawamura and Imagawa worked with the organism and identified it as *R. akamushi*. This work was confirmed by Ogata who retained the original name *R. tsutsugamushi*. There is excellent reason to believe that these organisms are identical. Lewthwaite and Savor did exhaustive cross-immunity tests and showed the similarity between scrub typhus fever and tsutsugamushi disease by both intraocular and intradermal reactions in rabbits and monkeys. From cross-protection tests between the rickettsias of Samatran fever and the tsutsugamushi disease of British Malaya performed on monkeys and rabbits it appears that these diseases are identical. In addition to these reasons, it should be borne in mind that travel in those parts of the world is sufficiently great so that persons could easily be transported to those areas well within the period of communicability of this disease and infect the vector and animal reservoir.

In Japan the larval form of the harvest mite locally known as the kedani mite (*Trombicula akamushi*) is the vector of this disease. There are several species and variants within species of trombicula, and they may be vectors in different localities. Little is known of the habits of the trombicula. The larvae are microscopic six-legged creatures that move along the ground or cling to the vegetation until they attach themselves to a passing man, bird or animal. The eggs are laid 8 to 10 cm. under the surface of the ground and when hatched pass through several stages to the adult form. Animal and bird life is abundant in Australia and the islands of the Southwest Pacific and provides the necessary blood meal for these larval mites. The evidence is that the larval mite is infected from the parent and passes the rickettsia on to man. Much work is needed before a final answer can be given on the relation between the several variants of trombicula. At least three species are under suspicion by the Australian and United States Army medical officers. The trombicula larvae attack man on all parts of the body, but the most frequent sites are the scrotum, groin and armpits. Numerous ticks are found in Australia and the islands of the Pacific and until proved innocent should be regarded as additional vectors.

Rats are abundant in the islands of the Pacific, and it appears likely that the local rat is the principal reservoir. Gunther, however, has listed some seventeen hosts for the larval mite. These include such birds as the bush fowl, swamp hen and parrot. It seems probable that migratory wild fowl are likewise hosts and spread the mites from one island to another. Lizards are frequent in these islands and also have been known to be infested with mites.

Ahlén and Lipshutz have recently reported on a series of 70 cases of tsutsugamushi fever in the Southwest Pacific. The most frequent location of the primary lesion was the scrotal area, although the inguinal and ankle areas were frequently involved. The incubation period was seven to fourteen days. The patients complained of frontal headache, generalized aches and pains, backache, weakness, insomnia, chilliness and fever that rose slowly to a peak of 104 to 105°F. within ten days. The pulse was slow in proportion to the temperature rise. The temperature fell by lysis. A small number of patients complained of pain in the abdomen, with nausea and vomiting and occasional diarrhea. The ulcer varied in diameter from a few millimeters to 1 cm. It was characterized by a central black necrotic area and was surrounded by an indurated, red areola. In some cases a lymphangitis was observed. The lymph nodes were the size of a walnut and smooth and tender and were not attached to adjacent nodes. They did not suppurate. The adenitis appeared from three to four days after the onset of symptoms. Conjunctivitis with mild edema of the eyelids was present. Weakness and general myatonia were pronounced. A pale, raspberry-colored erythematous rash, patchy in nature, was observed on the face, chest and abdomen and appeared about the fourth day. Sixty-seven per cent of the patients showed signs of severe atypical pneumonia, with a dry cough, scanty expectoration, dyspnea and tightness over the sternum. In a few cases there was evidence of consolidation. X-ray examination of 20 per cent of the cases showed atypical virus-like pneumonia. Epistaxis was seen in 20 per cent of the cases. Conjunctival hemorrhage occurred. Abdominal distention with nausea and vomiting was found in 60 per cent, and auditory disturbance in 34 per cent, with marked diminution of hearing to almost complete deafness. Hallucinations, disorientation, insomnia and nervousness were outstanding features. The fever continued for ten to fourteen days, during which time the patients were extremely weak and perspired profusely. Myocardial damage was observed late in the disease. In 3 per cent of the cases it was manifested by gallop rhythm, reduplication of the mitral first sound and muffled apical sounds, which were regarded as poor prognostic signs, and it was present in the one death that occurred. The specific agglutination test against the OXK strain of proteus bacillus became

sitive about the end of the second week. A few
ses never became positive. Convalescence was
olonged.

The American literature contains no reports of
distinctive gross lesions. Lewthwaite in his study
rural tropical typhus fever in the Malay Penin-
ula found petechial hemorrhages in the heart,
ngs, alimentary tract and kidneys. The brain
owed perivascular infiltrations more especially
equent in the pons and medulla and also occurring
the cerebellum. Thrombus formation was noted
some of the capillaries.

In the endemic area the diagnosis should not be
difficult, since the history and initial lesion are
uite helpful. The presence of OXK and the ab-
ence of OX2 and OX19 agglutinins should clear
he diagnosis.

It is generally agreed that the most important
ector in the treatment of tsutsugamushi disease
absolute bed rest and symptomatic treatment.
here is a difference of opinion about the adequacy
f acetylsalicylic acid in the control of headache.
hlum and Lipshutz discontinued the use of codeine
ecause of abdominal distention, which interfered
ith fluid intake. Several Australian medical
fficers found acetylsalicylic acid inadequate. Gen-
rally the patients with pneumonic signs were given
ne of the sulfonamide drugs in adequate doses, with
o appreciable results. All agree that there is a
itamin deficiency. The use of digitalis was dis-
appointing, as was the use of oxygen. The use of
edatives in adequate doses cannot be overrated.

Convalescent serum was considered, but was
ot used because there is no exact knowledge when
he blood is free of rickettsias and because of pos-
sible shock following its use.

The wearing of mite-proof clothing has been
recommended by the Japanese and others, but
anyone who has attempted to work in the endemic
areas of the tropics will realize that this measure
s impractical. Excellent results from the use of
insect repellents have been reported by the Aus-
tralian medical authorities. Camp sites should be
carefully selected and if possible be prepared by
natives. The grass should be cut to destroy the
habitat of possible vertebrate reservoirs and mites.
Rigid control of rats is necessary. Men should be

provided with hammocks and should not sleep on
the ground. Spraying the ground with a petroleum
emulsion of one of the new insecticides should be
considered. The value of any repellent is in its
proper use. Those exposed in an endemic area
should be carefully instructed in the use of repel-
lents and especially told to dust their socks and
trousers carefully. If the clothing is thoroughly
treated with insecticide there is no reason to expect
a mite to pass through its meshes.

TRENCH FEVER

During World War I trench fever was known as
five-day or Wolhynia fever. This disease dis-
appeared after the war and its true relation with the
rest of the rickettsial diseases is unknown. It is
louse borne and extracellular rickettsias have been
found in lice fed on patients ill with this disease.
Rickettsias are found in the feces of lice fed as
indicated. There is no report of agglutination of
X strains of proteus bacillus by patients' serums.
The incubation period is from five to twenty days.
The onset is sudden, with a quick rise of temper-
ature, which may last from a few days to over a
week. A number of relapses is the rule, which makes
this an important contributor to lost days. There
is no specific treatment. Prevention is by control
of lice.

The specific agglutination test against the OXK strain of proteus bacillus became

old theory that constipation is responsible. This ancient idea has been kept alive in modern times by equally vigorous advertising. There was no case in this series in which weakness or fatigue could be blamed on constipation. Although it may be true that some people have an increased sense of well-being with daily evacuation of the bowels, ill effects from so-called "poor elimination" have been tremendously exaggerated.

A sluggish liver has frequently been blamed for lack of energy, a charge of which this important

General weakness is generally blamed on a weak heart, but all cardiologists agree that this is not a frequent symptom of heart disease. In this series it occurred in only 8 cases (3 per cent). In the majority of cases, heart disease brings about other symptoms that cause the patient much more concern, such as dyspnea, pain in the chest and swelling of the feet. It should be pointed out that when a patient with a heart lesion complains only of weakness, this symptom is not likely to have any relation to the heart. In cases of neurocirculatory

lack of energy are likely to appear. Yet it has been observed that patients who have had jaundice may continue to feel weak for many months afterward.

Cancer is frequently feared when chronic ill health of any kind appears, but it was found in only 2 cases (0.7 per cent). Cancer seldom causes weakness and exhaustion unless it is so far advanced that anemia or cachexia has resulted. Carcinoma of the cecum or ascending colon may lead to advanced anemia before other symptoms have attracted attention, but as a rule other symptoms precede and supersede in importance the complaint of weakness. With Hodgkin's disease, chronic ill health with lack of energy is often the dominant complaint.

CURRENT MEDICAL OPINION

A comparison of these actual observations with current medical opinion regarding the causes of weakness and fatigue also shows important differences.

THE DIFFERENTIAL DIAGNOSIS OF WEAKNESS AND FATIGUE*

FRANK N. ALLAN, M.D.†

BOSTON

ONE of the problems most frequently encountered by the general practitioner and the internist is a complaint variously described as weakness, exhaustion, fatigue, loss of ambition, low vitality or weak spells. Weakness and fatigue, alone or dominating a group of other symptoms, cause thousands of people to suffer disability and a greatly lessened enjoyment of life. What can the physician do to investigate these complaints and how can he determine their cause? To present an answer to this question from our experience at the Lahey Clinic, data have been compiled on 300 consecutive cases in which weakness, fatigue or weak spells were the chief complaint.

RESULTS

In 61 cases (20 per cent), the complaint was caused by a physical disorder (Fig. 1). In 239 cases (80 per cent), it was apparently not due to a physical disorder but was the result of a nervous state of one kind or another. Weakness due to hunger and fatigue caused by hard labor were not encountered. However widespread these conditions may be, they are not likely to bring the patient for medical attention.

Of the 61 cases in which a physical disorder was found to be the cause of weakness, it was possible in 28 cases to make the diagnosis by clinical observation alone, the history and physical findings pointing to the cause and nature of the disorder. In 20 cases, the disease was hidden and the diagnosis could not be made without laboratory tests or roentgenograms. Thirteen cases were on the borderline, and special laboratory work or roentgenograms were needed to confirm or disclose the diagnosis.

An analysis of the physical disorders causing weakness and fatigue represented by this series is shown in Figure 2. Chronic infections, including tuberculosis, and even more frequently nontuberculous pulmonary infection, sometimes in the convalescent period, were found in 13 of the 300 cases (4 per cent). Metabolic disorders were found in 12 cases (4 per cent)—8 of diabetes and 4 of myxedema. In 8 cases (3 per cent) there was heart disease. In 16 cases (5 per cent) there were neurologic disorders including 4 cases of *myasthenia gravis*, 8 of narcolepsy and 3 classified as psychomotor epilepsy. Anemia of different types was found in 5 cases. Miscellaneous causes accounted for the remaining 4 cases, including 1 each of carcinoma of the lung, vitamin deficiency, recurrent fever possibly due

to Hodgkin's disease and unclassified low-grade fever.

It should be noted that complex problems and unusual conditions are more likely to be seen in hospital or clinic work than in general medical practice. Furthermore, a relatively small series such as this one can give only the general trend of distribution of cases. A larger one would almost certainly

FINDINGS IN 300 CASES

FIGURE 1.

include important disorders that were not present in this group, such as Addison's disease and subacute bacterial endocarditis. Yet these observations give a fair picture of what the physician may expect to encounter when consulted by a patient who complains of weakness.

CURRENT LAY OPINION

If these causal conditions are compared with those usually blamed for weakness and fatigue, a considerable deviation from current lay and medical opinion is noted (Table 1). In the minds of the public, lack of energy tends today to mean lack of vitamins. This idea has been exploited by the manufacturers of vitamin products. Our experience lends no support to the theory that vitamin deficiency seriously affects the health of a large percentage of the population. In this representative group of 300 cases there was only 1 in which vitamin deficiency was held responsible for weakness.

The concept of vitamin deficiency as a cause of lack of energy has now surpassed the still widely

*Presented at the annual meeting of the Massachusetts Medical Society, Boston, May 24, 1944.

†Co-director, Department of Internal Medicine, Lahey Clinic.

orning and decreases during the day; when days with excellent vigor are followed by days of exhaustion, with no change in activity to account for such a difference; when immediate benefit follows the use of a medication that has a slow pharmacologic action such as vitamins, thyroid, iron, liver extract and digitalis; when the weakness immediately returns on the omission of the customary treatment with these drugs for a single day; when the patient never has felt really well; when he has been tired and weak for over three years without

ing from benign forms of nervousness that were classified as chronic nervous exhaustion when extreme and simply as nervous fatigue when of milder degree (Fig. 3). The percentage of neurotic patients must be higher than actually exists in the general run of people who have these complaints, because such patients are much more likely than others to seek medical advice. It is important to distinguish the true neurosis from what may be called "benign nervousness," because the treatment must be planned differently (Table 2). A neurosis

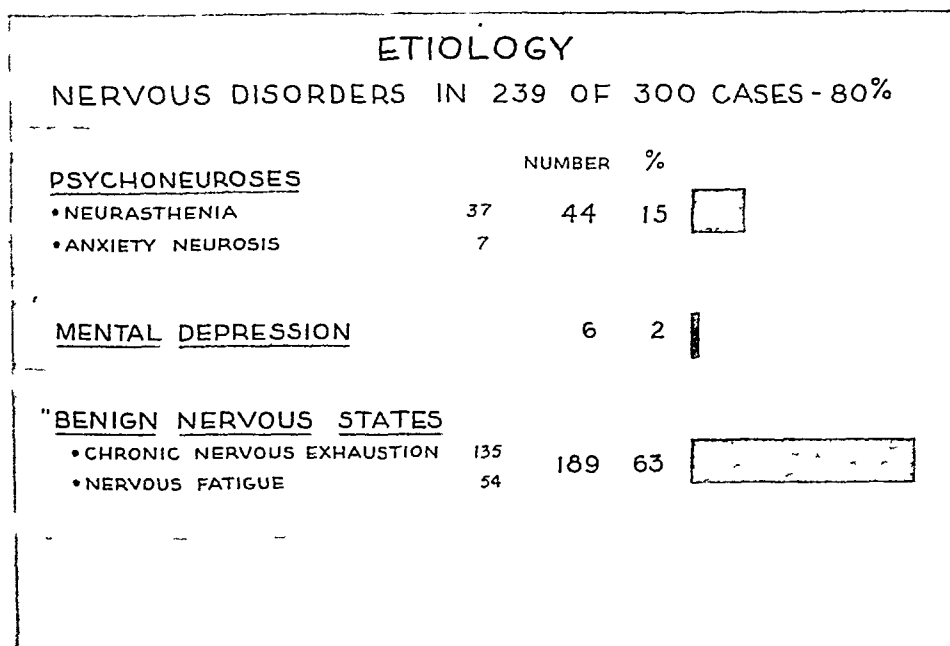

FIGURE 3.

evidence of a physical disorder; when he complains of nervousness, anxiety and worry and has symptoms that are obviously of nervous origin, such as a lump in the throat, tension in the back of the neck, difficulty in getting a satisfying breath or palpitation, when he denies a nervous state but reveals it by a multiplicity of complaints, variation in emphasis on different symptoms, vagueness of description and nervous behavior, such as flushing and weeping. One must give some attention also to a family history of nervous breakdowns and to a personal history of excessive nervous strain, but these should not be given so much weight as the other factors mentioned.

CLASSIFICATION OF NERVOUS STATES

There is need for discrimination in dealing with the nervous states responsible for weakness and fatigue. One should certainly not assume that any nervous condition represents a neurosis. Only one fifth of the patients with nervous disorders were frankly neurotic. The remainder were suffer-

ing from benign forms of nervousness that were classified as chronic nervous exhaustion when extreme and simply as nervous fatigue when of milder degree. The patient with the latter is born with a constitution no different from the average, but he comes to suffer from nervous fatigue or

Reaction to reassurance	Disappointment	Satisfaction

exhaustion because of special stress and strain, overwork, excessive worry or loss of sleep. If he is assured that the physical examination has shown no disorder, he expresses satisfaction. The reaction of the neurotic patient, on the other hand, is one of disappointment. He stresses the serious-

One finds *anemia* high on the list of conditions often treated for the complaint of weakness. It was found in only 5 cases (1.7 per cent). Attention is sometimes wrongly focused on minor deviations from the normal in the hemoglobin and red-cell count. Furthermore, the frequently used Tallqvist test for hemoglobin may give fallacious readings. In general, one may safely say that anemia does not cause weakness unless the hemoglobin drops below 70 per cent and the red-cell count well below 4,000,000.

A diagnosis of *low blood pressure* is often made when the blood-pressure readings are actually within normal range. Too much attention has been paid to possible ill effects of a systolic blood pressure below 110. Intensive treatment is often undertaken to raise it, and one finds expression of satisfaction because of a rise in pressure from 105 to 115. Perfect health and vigor are compatible with a systolic blood pressure as low as 90, and on the average the expectation of life is longer with the blood pressure at the lower range of normal. High blood pressure is sometimes also blamed for lack of energy, but when a hypertensive patient complains of lack of energy it is more likely to be due to increased nervous tension than to increased vascular tension. In none of these cases was weakness related to the blood pressure.

Myxedema was responsible for lack of energy in 4 patients (1 per cent), but this must be higher than the incidence in ordinary practice. A diagnosis of thyroid deficiency is often mistakenly made because the patient feels tired and looks fat and the basal metabolic rate is -15 or -20 per cent. Deviations from the standard rate may be found in many healthy people. A low basal metabolic rate not related to thyroid deficiency is seldom accompanied by any change in health, but there are a few patients who have diminished energy. The diagnosis of thyroid disease should not be made unless a low metabolic rate is accompanied by clinical evidence of the condition. If there is any doubt, a determination of the blood cholesterol level may aid the diagnosis more conclusively than does the basal metabolic rate. The blood cholesterol is almost invariably above normal in the presence of hypothyroidism; if one finds a low metabolism without high blood cholesterol, thyroid disease can usually be excluded.

Hyperthyroidism causes weakness, but it is seldom the chief complaint except in the severe long-standing cases and in the apathetic cases of old age.

Addison's disease is manifested by the most extreme weakness, but it is a rare disease. In far-advanced cases, the diagnosis readily is made from the clinical picture, including abnormal pigmentation, hypotension, gastrointestinal disturbances and loss of weight, in addition to the asthenia. In early or borderline cases the diagnosis may be aided by special tests. One of these, introduced by Kepler

and his co-workers,* is simple and easy to perform. The patient restricts his fluid intake and saves all the urine passed during the night for a period of nine hours. The following morning he is given four to six glasses of water (9 cc. per pound of body weight), and the excretion of urine is measured each hour for four hours. If the excretion in any one hour exceeds the total volume of urine excreted during the night, Addison's disease can be excluded. If there is a low excretion, Addison's disease may be present, but to rule out other conditions that may interfere with water balance, further study is needed.

Other *endocrine conditions*, especially pluriglandular disorders, are often blamed for fatigue. There is seldom any sound basis for the diagnosis, although in a few cases of pituitary tumor lack of energy is indeed an early sign.

Undulant fever is currently given a great deal of attention in certain parts of North America. It must be considered in any case of long-continued fever or ill health, but the diagnosis should not be made on insufficient evidence. Positive agglutination reactions, unless in a high titer, and positive skin tests should not alone decide the diagnosis. In the absence of a history of acute or subacute febrile illness some time in the course of the disorder, the diagnosis is open to question.

DIAGNOSTIC STUDIES

Investigation of the complaint of weakness, fatigue or lack of energy must begin with a review of the history from every standpoint. Patients often fail to mention even significant symptoms. The detailed history must be followed by a careful physical examination. The history and examination should enable one to make a complete diagnosis in about half the cases in which a physical disorder is responsible for the complaint. It should also enable one to suspect hidden or practically hidden disease and should furnish clues to the complete diagnosis.

It is often assumed that the diagnosis of a nervous state must be deferred until the examination, laboratory tests and roentgenograms have ruled out a physical cause for the complaint. This is the wrong point of view. The diagnosis of a nervous state should be made by direct observation of the characteristics of such condition and not be reached entirely by exclusion. If the patient has a physical disorder and a nervous state, they must both be recognized and evaluated in order to make a complete diagnosis and to undertake effective treatment.

CHARACTERISTICS OF NERVOUS STATES

One must suspect that weakness and fatigue are due to a nervous state under the following circumstances: when the lack of energy is greatest in the

*Robinson, F. J., Power, M. H., and Kepler, E. J. Two new procedures to assist in recognition and exclusion of Addison's disease. *Proc. Staff Meet., Mayo Clin.* 16:577-583, 1941.

morning and decreases during the day; when days with excellent vigor are followed by days of exhaustion, with no change in activity to account for such a difference; when immediate benefit follows the use of a medication that has a slow pharmacologic action such as vitamins, thyroid, iron, liver extract and digitalis; when the weakness immediately returns on the omission of the customary treatment with these drugs for a single day; when the patient never has felt really well; when he has been tired and weak for over three years without

ing from benign forms of nervousness that were classified as chronic nervous exhaustion when extreme and simply as nervous fatigue when of milder degree (Fig. 3). The percentage of neurotic patients must be higher than actually exists in the general run of people who have these complaints, because such patients are much more likely than others to seek medical advice. It is important to distinguish the true neurosis from what may be called "benign nervousness," because the treatment must be planned differently (Table 2). A neurosis

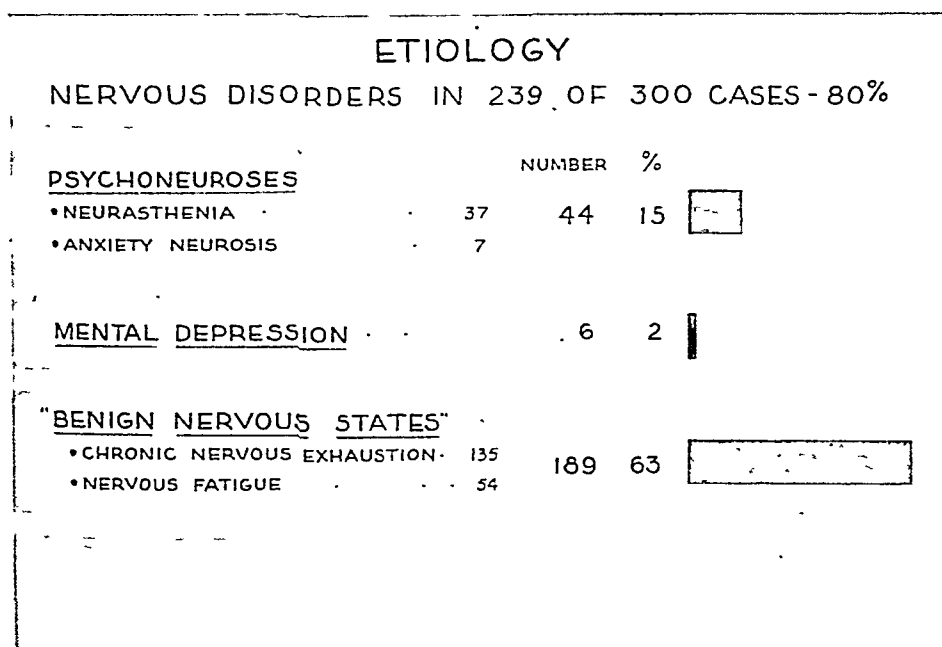

FIGURE 3.

evidence of a physical disorder; when he complains of nervousness, anxiety and worry and has symptoms that are obviously of nervous origin, such as a lump in the throat, tension in the back of the neck, difficulty in getting a satisfying breath or palpitation; when he denies a nervous state but reveals it by a multiplicity of complaints, variation in emphasis on different symptoms, vagueness of description and nervous behavior, such as flushing and weeping. One must give some attention also to a family history of nervous breakdowns and to a personal history of excessive nervous strain, but these should not be given so much weight as the other factors mentioned.

is largely dependent on intrinsic factors, whereas a benign nervous state is largely dependent on extrinsic factors. The patient with the latter is born with a constitution no different from the average, but he comes to suffer from nervous fatigue or

TABLE 2. *Differential Diagnosis of Neurosis and "Benign Nervousness."*

DATUM	NEUROSIS	BENIGN NERVOUSNESS
Etiology	Largely intrinsic	Largely extrinsic
Background	Constitutional inadequacy	Average
Family history	Nervous breakdown (frequent)	Average
Multiple complaints	Usual	Unusual
History	Changeable	Consistent
Onset	Vague	Fairly definite
Duration	Often since childhood	Limited
Reaction to reassurance	Disappointment	Satisfaction

CLASSIFICATION OF NERVOUS STATES

There is need for discrimination in dealing with the nervous states responsible for weakness and fatigue. One should certainly not assume that any nervous condition represents a neurosis. Only one fifth of the patients with nervous disorders were frankly neurotic. The remainder were suffer-

ing from exhaustion because of special stress and strain, overwork, excessive worry or loss of sleep. If he is assured that the physical examination has shown no disorder, he expresses satisfaction. The reaction of the neurotic patient, on the other hand, is one of disappointment. He stresses the serious-

ness of his complaints and insists that some abnormality must be found to account for them.

DIAGNOSTIC PROCEDURES TO IDENTIFY PHYSICAL DISORDERS

To make a complete search for physical disorders, various methods of investigation may be undertaken. These should include in all cases urinalysis and the usual blood tests, such as the red-cell and white-cell counts, examination of the blood smear, determination of the hemoglobin and the Hinton, Wassermann or other test for syphilis. The routine urinalysis may lead to the discovery of diabetes, which can be recognized in no other way. In about half the cases of diabetes seen at the Lahey Clinic, typical diabetic symptoms and complications are absent. The urinalysis may also reveal nephritis and pyelitis. The blood test may disclose primary blood disorders and changes secondary to systemic infection or other disease.

A roentgenogram of the chest is obligatory for all young people who feel tired and for people of any age who have a past history of pleurisy, contact with tuberculosis or respiratory symptoms such as cough. If any hidden infection is suspected, a daily record of the body temperature should be kept for three days or more. The blood-sedimentation rate should be determined, and also the agglutination test for undulant fever when the past history suggests the possibility of infection of this type. Blood-sugar tests should be made when the relation of symptoms to lack of food and to exertion arouses suspicion of hypoglycemia. The basal metabolic rate and the blood cholesterol test aid in the diagnosis of weakness due to thyroid disease, the adrenal-function test of Kepler and his co-workers in cases of suspected Addison's disease, and roentgenograms of the head in detecting enlargement of the sella in cases of tumor of the pituitary gland.

Laboratory tests for vitamin deficiency have not received widespread clinical application. As a

rule, a therapeutic test is the best support now available for the clinical diagnosis of hypovitaminosis, although far too often the results are not subject to a control test.

In the neurologic field the prostigmine and quinine tests for myasthenia gravis and the electroencephalogram are available.

CONCLUSIONS

In a series of 300 cases in which medical examination was requested because of weakness, fatigue and weak spells, the complaint was found to be caused by a physical disorder in 20 per cent. In the remainder the complaint was not caused by any physical disturbance but was the result of a nervous state. This was classified as a neurosis in approximately 20 per cent, and as a benign nervous state, chronic nervous exhaustion or nervous fatigue in the rest of the cases.

In nearly half of the cases in which a physical disorder was found to be the cause of weakness, it was possible to make a positive diagnosis by clinical observation alone. In the others, laboratory tests or roentgenograms were essential to reveal a hidden disease or confirm the diagnosis. The most frequent physical disorders were chronic infection, diabetes, heart disease, various neurologic disorders and serious diseases of the blood. Certain conditions, such as vitamin deficiency and glandular disorders, considered widespread causes of weakness by both the laity and the medical profession, were actually found to be rare, and not a single case of weakness due to liver trouble, poor elimination or low blood pressure was encountered.

The study of weakness and fatigue leads to a consideration of medical problems covering almost every field of medicine. Although a high percentage of patients with these complaints have no physical disorder, there is a group in which physical conditions of unusual interest may be discovered. In any case these symptoms warrant thorough and complete investigation.

EXTRARENAL TUBERCULOUS LESIONS ASSOCIATED WITH RENAL TUBERCULOSIS

DAVID S. CRISTOL, M.D.,* AND LAURENCE F. GREENE, M.D.†

ROCHESTER, MINNESOTA

RENAL tuberculosis is too often symptomatically silent during the time when it can be treated most successfully. Although the diagnosis of this condition can be made most satisfactorily by the identification of the organism in the urine and can be confirmed by inoculation of laboratory animals, in many cases the disease escapes recognition in its early stages simply because tuberculous infection is not suspected. Hence any symptom, sign or roentgenographic or laboratory finding that may cause one to suspect the diagnosis of renal tuberculosis is worthy of investigation or evaluation.

CALCIFIED MESENTERIC LYMPH NODES

Calcified mesenteric lymph nodes are seen frequently in the routine roentgenograms of the urinary tract. They usually attract attention only when they are so situated as to make it necessary for them to be distinguished from urinary calculi. This is only rarely essential. Although there are several conditions believed to be responsible for the pathologic change in the lymph nodes that is followed by calcification, the vast majority of calcified mesenteric lymph nodes have been the seat of tuberculous infection. This fact prompted us to study the incidence of calcified mesenteric lymph nodes in cases of proved renal tuberculosis. To accomplish this, we carefully examined the intravenous urograms and retrograde pyelograms in 145 consecutive cases of proved renal tuberculosis, in each of which nephrectomy had been performed, so that hence a pathological as well as a bacteriologic diagnosis had been made. This series was compared with a series of 145 consecutive cases of surgically treated renal

TABLE 1. Incidence of Calcified Mesenteric Lymph Nodes in Cases of Renal Tuberculosis and of Nontuberculous Renal Lithiasis

PATIENTS	RENAL TUBERCULOSIS		NONTUBERCULOUS KIDNEYS	
	NO. OF CASES	PERCENTAGE	NO. OF CASES	PERCENTAGE

With calcified mesenteric lymph nodes	8	10	3	3
Women:	64		52	
With calcified mesenteric lymph nodes	11	17	5	10
Totals	145		145	
Percentages		13		6

lithiasis in many of which nephrectomy was performed and in each of which the diagnosis of renal tuberculosis was excluded.

Table 1 shows the incidence of calcified mesenteric lymph nodes in both series of cases. Calcified

mesenteric lymph nodes were found to be present in 13 per cent of the roentgenograms of patients suffering from proved renal tuberculosis. This incidence was more than twice that found in a comparable series of patients not suffering from renal tuberculosis.

TUBERCULOUS EPIDIDYMITIS

Although it is generally known that renal tuberculosis is fairly frequently accompanied by genital tuberculosis, too often intractable epididymitis is treated for long periods before the kidneys are investigated.

In 34 (42 per cent) of the 81 male cases of proved renal tuberculosis incorporated in the preceding study, genital tuberculosis also was present (Table 2). None of the 93 male subjects in the control group suffered from inflammation of the genitalia.

TABLE 2. Incidence of Tuberculous Epididymitis and Prostatitis in Cases of Renal Tuberculosis and of Nontuberculous Renal Lithiasis.

GENITAL INVOLVEMENT	RENAL TUBERCULOSIS		NONTUBERCULOUS KIDNEYS	
	NO. OF CASES	PERCENTAGE	NO. OF CASES	PERCENTAGE
Tuberculous epididymitis	31	38	0	0
Tuberculous prostatitis	3	4	0	0
None	47	58	93	100
Totals	81		93	

Thirty-one of the 34 patients had proved tuberculous epididymitis, and the remaining 3 were believed to have tuberculous prostatitis. In 15 of these cases it was necessary to remove the kidney on the same side as the involved epididymis, and in 7 cases the kidney on the opposite side from the involved epididymis was removed. In 9 cases both epididymides were involved.

The frequency of concomitant genital and renal tuberculosis is so great that the genitalia of every male patient complaining of urinary symptoms should be carefully examined for evidence of tuberculosis. Although renal tuberculosis frequently occurs in the absence of genital tuberculosis, the latter is accompanied more often than not by renal tuberculosis. Every male patient who has epididymitis of possibly tuberculous nature should therefore receive complete urologic investigation, even in the absence of urinary symptoms. In this manner the early renal lesions of tuberculosis may be detected.

PULMONARY TUBERCULOSIS

Since we share the general opinion that renal tuberculosis largely if not entirely represents a

*Fellow in urology, Mayo Foundation.

†Instructor in urology, Mayo Foundation; member, Section on Urology, Mayo Clinic

secondary hematogenous focus of tuberculous activity resulting from a primary pulmonary infection, we decided to investigate the incidence of pulmonary involvement in these 290 cases. To do this we reviewed the pulmonary roentgenograms of the 145 proved renal tuberculous patients and the 145 control patients suffering from operative renal lithiasis. As shown in Table 3, each case was relegated to one of three categories: first, the healed

TABLE 3. *Incidence of Pulmonary Tuberculosis in Cases of Renal Tuberculosis and of Nontuberculous Renal Lithiasis.*

THORACIC INVOLVEMENT	RENAL TUBERCULOSIS		NONTUBERCULOUS KIDNEYS	
	NO. OF CASES	PERCENT-AGE	NO. OF CASES	PERCENT-AGE
Healed or active adult type	50	34	6	4
Healed childhood type (Ghon complex)	20	14	20	14

Totals	145		145	

or active adult type of tuberculosis; second, the healed childhood type of tuberculous infection, which often is referred to as the Ghon complex; and finally, those cases not showing any pulmonary pathologic change whatsoever, which were designated as negative.

The findings clearly demonstrate the frequency with which renal tuberculosis is associated with healed or active adult-type pulmonary tuberculosis. It is of incidental interest that the frequency of the healed childhood type of tuberculosis was the same in the two series.

SUMMARY AND CONCLUSIONS

The diagnosis of renal tuberculosis can be established relatively easily once this disease is suspected. Too frequently this condition, whose successful treatment depends on its early diagnosis, is not considered. The incidences of three easily demonstrable tuberculous lesions that are associated with renal tuberculosis have been determined. The presence of either of these associated conditions should cause one at least to suspect renal tuberculosis.

Since roentgenographically evident calcified mesenteric lymph nodes are more than twice as frequent in cases of proved renal tuberculosis as in a control nontuberculous group of patients, the presence of calcified mesenteric lymph nodes in the roentgenogram of a patient suffering from a urologic disease should cause one to consider the diagnosis of renal tuberculosis.

Since epididymitis occurred in 38 per cent of 81 cases of renal tuberculosis but did not occur in a control group of 93 cases, every case of intractable epididymitis should be considered tuberculous until proved otherwise. The condition of the kidneys of such a patient should be promptly evaluated.

Since roentgenographic evidence of healed or active adult type of pulmonary tuberculosis is more than eight times as frequent in cases of renal tuberculosis as in a comparable control group, in every case of renal tuberculosis the patient should have the benefit of a stereoroentgenogram of the thorax. Furthermore, renal tuberculosis should be excluded in any case of pulmonary tuberculosis in which there are subjective or objective urinary findings.

MEDICAL PROGRESS

MODERN CONCEPTS OF RENAL STRUCTURE AND FUNCTION IN CHRONIC BRIGHT'S DISEASE*

STANLEY E. BRADLEY, M.D.†

BOSTON

DURING recent years an intensive application of well-established methods of micromorphology has broadened considerably the knowledge of the anatomic patterns of renal disease. Likewise, great strides have been made toward an understanding of renal pathologic physiology through the development of new functional tests. These two avenues of approach have converged on the central problem of the relation between renal structure and function, and when integrated, allow insight into some of the more remote physiologic disorders and clinical manifestations of renal disease. It is the purpose of this review to discuss recent advances in the pathology and physiology of the kidneys as affected by the various forms of Bright's disease.

STRUCTURE

Factors capable of deforming the architecture of the kidney include vascular disturbances, interstitial tissue proliferation and nephron damage. The last may be secondary to the direct action of noxious agents, to ischemia, to blockage by casts and to the mechanical effects of scar tissue. These factors operate to some extent in all forms of chronic renal disease at a tempo depending on the nature of the primary process, so that each type of disorder is characterized by a distinctive pathology of structure and function, at least early in the course of the disease. In the terminal stages, however, there is a tendency to develop a final common pattern, probably because the same fundamental processes are active in all. Clinically, also, the terminal picture in all forms of Bright's disease is similar.

Vasculature

Vascular changes play a prominent role in the disorganization of renal anatomy. Vascular rearrangement of itself necessarily causes architectural disorder with resulting disturbances in blood supply that directly affect the parenchyma. In all forms of chronic renal disease, the vascular pathology appears to be fundamentally similar but the extent to which it dominates the picture depends on the etiology. In the kidney of essential hypertension it is of prime importance; in glomerulonephritis it is

of considerably less importance; and in certain nephroses it is, at first, apparently of little or no importance. In all, however, with time and progression, vascular alterations occur and probably contribute to further damage.

The unique circulatory pattern of the kidney is such that interference with the flow of blood through the glomerulus would be expected to disturb the flow through the peritubular capillaries and cause damage to the attached tubule. This surmise has been supported by the finding that direct communications between the interlobular or arcuate arteries and the peritubular capillaries are absent, or at least exceptional, in the normal kidney.¹ Thus it has seemed reasonable to explain tubular damage in glomerulonephritis and nephrosclerosis on the basis of glomerular obstruction and the resultant ischemia and atrophy of the attached tubule.² Recently, however, in aged persons many direct arterial communications with the postglomerular circulation have been found,¹ and in chronic renal disease it has been shown that glomerular patency is not necessary for an efficient circulation of blood through the peritubular capillaries.³⁻⁵

Oliver and his co-workers³ have demonstrated that direct arterial connections with the peritubular capillaries appear in larger and larger numbers as glomerular damage increases. These communications spring from the arcuate and interlobular arteries and from the afferent arterioles. The latter types appear to be of special importance. First observed by Isaacs in this country and later by Ludwig, they have come to be called Isaacs-Ludwig arterioles or simply Ludwig's vessels.⁶ A Ludwig vessel comes off the afferent arteriole perpendicularly or obtusely and straightway enters the tubular capillaries by-passing the glomerulus. Preceding the development of this collateral circulation there is thickening of the basement membrane, proliferation of extracapillary connective tissue and capillary endothelium and an occlusion of glomerular capillary loops.³ Additional obstruction to flow of blood through the glomeruli has been attributed to deformation of the corpuscle by the overgrowth of interstitial elements, and by hypertrophic or hydronephrotic tubules.³ When amyloidosis is the cause of chronic renal disease, amyloid material may be found about the cells of the subintimal layers,⁷ at first in discrete deposits, which later coalesce to produce rigidity and luminal narrowing and, in

*From the Evans Memorial, Massachusetts Memorial Hospitals, and the Department of Medicine, Boston University School of Medicine.

†Instructor, Department of Medicine, Boston University School of Medicine; assistant physician, Evans Memorial, Massachusetts Memorial Hospitals.

the glomerulus, occlusion of the loops. In addition, the capillary networks become thicker and the large vessels are more sharply defined by parietal changes, until the parenchyma of the kidney seems to rest upon a scaffolding of numerous relatively rigid vessels.⁸ In all types of chronic renal disease intimal thickening and deposits of lipoidal material contribute to vascular rigidity. Vessels may be formed *de novo* but mainly seem to be derived from pre-existing channels. Thus, after infarction the newly appearing collateral vessels arise largely from a remodeling of those already present.⁹ Spanner¹⁰

doubt that certain unusual cells appear among the myocytes in the media of renal arteries and arterioles and are particularly numerous close to the junction of the afferent arterioles and the malpighian corpuscles in mice, rats, dogs, cats, rabbits, ferrets and man.¹¹ They are, however, variously described, and it is questionable whether they are identical structures in the various species and whether more than one type occurs. Close to the glomerulus (Fig. 1) the internal elastic membrane may disappear and the media may be replaced by a thick sheath of cells, somewhat larger than myocytes,

FIGURE 1. Schematic Representation of a Typical Human Nephron Showing the Important Structures.

The juxtaglomerular apparatus and the macula densa of the distal tubule are shown in greater detail at the lower right.

has demonstrated arteriovenous anastomoses anatomically in the human kidney, and it has been suggested that retrograde perfusion of the peritubular capillaries through these structures may follow glomerular obstruction. Activity of these anastomoses, however, has not been observed in chronic disease,³ and they appear to be completely lacking in infarcted areas.⁹

Juxtaglomerular Apparatus

Interpretation of the histologic structure of the afferent arteriole remains as confused as it was when Smith⁶ reviewed the subject at some length in his Harvey Lecture of 1939. There seems to be little

that have a clear cytoplasm in which acidophilic granules may or may not be found. In the human kidney these granules may be fluorescent.¹² The cuff pouts out eccentrically at the point of junction with the capsule to form a polar pad (*Polkissen*) closely attached to a segment of the distal convoluted tubule. The distal tubular segment at this point shows crowding and increased height of the epithelial cells, the macula densa. The argument concerning the identity of the medial cells appears to revolve about the presence and character of granules that were absent in the cells of the *Polkissen* described by Zimmermann¹³ but present in the "epithelioid cells" described in the media by Ruyter,¹⁴ Oberling¹⁵

and Goormaghtigh¹⁶; they are large and striking in the mouse but small and inconspicuous in man. After further study this conflict may be resolved on the basis of the differences in species and of the various histologic methods employed. A number of workers have been struck by the resemblance of these cells to the "epithelioid cells" that invest the vessels in the normal glomus and appear so strikingly in glomus tumors.¹⁷ It is usually stated that these cells have a clear cytoplasm. Zimmermann¹⁸ denies that the cells observed by him were epithelioid in character and observed fine fibers that passed through the cytoplasm. He did, however, describe "pericytes" about the glomerular capillaries — cells apparently derived from the smooth muscle and capable elsewhere in the body of regulating capillary flow. Murray and Stout¹⁷ have recently shown that epithelioid cells from glomus tumors take on, in tissue culture, all the characteristics of the typical pericytes of Zimmermann. Hence, the possibility remains that the cells in question represent an intergrade in the transition between the smooth-muscle cells of the media of the afferent arteriole and the pericyte of the glomerular capillaries.

Goormaghtigh¹⁶ has named the structure at the terminus of the afferent arteriole the "myoneuro-arterial juxtaglomerular apparatus." Its description is germane to the present discussion because of the view expressed by Goormaghtigh^{18, 19} and others^{20, 21} that the structure is an endocrine organ, the probable site of renin formation. Opposed to this is the notion, based on the resemblance of the structure to glomic cells found at arteriovenous anastomoses in the digits and elsewhere, that it regulates the flow of blood through the glomerulus in response to nervous stimulation of the thick neural net associated with it, and to chemical stimulation of the macula densa by the urinary constituents.^{15, 22} The first hypothesis is supported by the finding of Goormaghtigh and Grimson,²³ confirmed by Graef,^{6, 11} that hypertrophy of the structure occurs during experimental renal hypertension and by their further finding, confirmed by others,^{20, 21} that hypertrophy of this structure occurs in essential hypertension, nephritis and eclampsia. Oberling,²² however, failed to find such hypertrophy frequent in hypertension but, on the contrary, noted degeneration and regression. He believes that the lesions described by Goormaghtigh are the result of hypertension and represent muscular hypertrophy and arteriosclerosis. Moreover, such hypertrophy is usually not striking or uniform, and it is an admittedly uncommon finding.¹⁰ The second suggestion lacks any supporting evidence, although an abundant innervation of the structure has been demonstrated.

Recently a singular case was reported by Graef²⁴ in which hypertrophy of afferent arteriolar medial cells presented the only pathological evidence of renal disease. The patient, a woman of thirty,

suffered from hematuria, proved to be unilateral. In the third month of pregnancy nephrectomy was performed on the basis of a diagnosis of renal neoplasm. The excised kidney appeared grossly normal, but microscopic examination revealed a striking change in all the arterioles, consisting of hypertrophy and hyperplasia of the medial cells with luminal constriction. These changes were especially marked at the point of entrance of the afferent arteriole into the glomerular network, where the hypertrophic changes were so extensive as to indent the glomerulus and surrounding tubules. All the cells were granular, and the cytoplasm was quite clear. Erosion of the pelvic and ureteral epithelium appeared to account for the hematuria. The subsequent course of this patient was of significance, for after an uneventful postoperative recovery, toxemia of pregnancy appeared in the ninth month of gestation, with proteinuria, hypertension, convulsions and coma. Recovery followed spontaneous delivery of a stillborn child. Hypertension continued to be present during the succeeding month and then the blood pressure returned to normal. Graef suggests that hormonal activity during pregnancy may be responsible for a change in vascular smooth muscle similar to the change in the myometrium.

Interstitium

In all forms of Bright's disease, active and passive alteration of the renal interstitial tissue is prominent. The disappearance of nephrons creates dead space filled by connective tissue, usually with thickening of the stroma by shrinkage rather than by proliferation. In addition to this passive increase in stroma there may be an active process of fibrous-tissue proliferation, probably in a large part secondary to inflammation, evident pathologically by the cellular infiltration. This is most profound in pyelonephritis or, as Bell²⁵ calls it, "exudative interstitial nephritis," where bacteria may be found exciting an inflammatory response to the point of abscess formation with sequential fibrous-tissue proliferation.²⁶ In glomerulonephritis, inflammatory changes ranging from edema and polymorphonuclear infiltration to fibroblastic proliferation with collagen formation and round-cell infiltration may be observed.³ The normally thin sheets of fibrous tissue are widened to thick bands, which may at first increase the bulk of the organ but later cause shrinkage by destruction of the nephrons. The fibrillae are obviously newly added for they are irregular and disoriented and soon enmesh tubules and glomeruli, producing by constriction all degrees of atrophy and distortion.³ It seems clear that here, as in pyelonephritis, the interstitial inflammatory reaction precedes any serious modification of the renal parenchyma. In the kidney of the hypertensive, however, where vascular changes are predominant early in the course of the disease, the in-

terstitial modification is fairly simple and is mainly secondary to parenchymal shrinkage, with approximation of fibrils causing increased density.³ Inflammation is seen frequently enough, however, in the hypertensive kidney to sustain the belief that here, too, it contributes to the interstitial disorder.^{3, 27} Terminally, in all, if the course is protracted, granulations of the surface appear where connective tissue collapses and contracts about still viable nephric units, which may be greatly hypertrophied, while the kidney becomes small and misshapen.

Parenchyma

The three dimensional reconstructions of renal micromorphology in Oliver's laboratory³ have thrown new light on nephron structure in disease. It has been shown that pathologic nephrons may be broadly divided into two categories, the atrophic and the hypertrophic.²⁸ The *hypertrophic* nephron shows a striking change, almost entirely limited to the proximal tubules, which may be increased in bulk as much as ten times the normal. Cellular hyperplasia, luminal dilatation and increased length, especially marked in the terminal broad segment, the so-called "spiral of Schachowa," with displacement of Henle's loop, account for the increase in size. The distal tubule may be normal or may show evidences of other types of pathologic change. The *atrophic* nephron exhibits an irregular diminution in the size and number of the tubular cells. This may be associated with dilatation or stenosis. Of course, there is a considerable degree of intergrading so that hypertrophy and atrophy may appear side by side in the course traced by the tubule through the kidney, or the degenerative change may be so extreme as to lead to destruction of the walls and fragmentation of the tubule. Disruption often occurs close to the glomerulus in the proximal convoluted tubule and is followed by healing with the formation of aglomerular nephrons and atubular glomeruli. Either may persist long after the remainder of the unit to which it was formerly attached has completely disappeared. The aglomerular tubule may be otherwise entirely intact and show all the possible changes of atrophy and hypertrophy. Fragmentation may result in the formation of islets of tubular tissue that appear as clusters of cells or, more frequently, as small cysts filled with hyaline material.³

Vascular pathology and interstitial tissue proliferation are major causes of the lesions, but other factors may be equally important. Agents capable of both damaging and stimulating the renal parenchyma may manifest themselves by decreases in mitochondria,²⁹ deposits of lipoidal material, cloudy swelling and even severer changes leading to cell death on the one hand and by increases in nuclei and hypertrophy of cells on the other. Many of

these cellular changes may precede significant ischemia or fibrosis. It is probable that unidentified toxins are concerned in glomerulonephritis, pyelonephritis and certain of the nephroses. To what extent associated endocrinopathies may contribute to this is unknown. It is certain, however, that the appearance of large amounts of protein in the glomerular filtrate is accompanied by intracellular deposits of hyaline and lipoid material. Evidence based on chemical and electrophoretic studies of urinary protein suggests that the beta-globulin fraction of the plasma protein is largely responsible for the formation of hyaline casts and blockage of the tubules both in nephritis and in the renal failure of multiple myeloma.³⁰⁻³²

Intratubular casts that occlude the lumens and cause hydronephrotic changes cannot be neglected as a potent cause of tubule alteration.³ Almost the total length of a tubule may be filled with solid substance. These consolidated masses seem to be clearly ante mortem in origin and not artifacts. Casts are usually heterogeneous conglomerates of solid material, granular or hyaline in appearance, probably derived from precipitated constituents of the glomerular filtrate and desquamated tubular epithelial cells; many contain red cells and leukocytes. In pyelonephritis the tubules are frequently packed with leukocytes enmeshed in a hyaline matrix.²⁶ Later the leukocytes disappear and many tubules, cyst-like in appearance, remain blocked with a bluish-staining colloid material. It is stated that such casts are distinctive and diagnostic of pyelonephritis.³³ Casts are found in the collecting tubules and distal convoluted segments, and granular material is occasionally seen in the loop of Henle, but the proximal segment usually remains empty. This finding is in accord with the view that concentration of the glomerular filtrate takes place in the distal tubule. Whether primary blockage occurs in the collecting tubules, — which are characteristically affected by the disease, causing kinking and coiling to trap the solid material, — or in the distal tubule is not settled, but it seems likely that, although it occurs more frequently in the former, than in the latter, obstruction of the distal tubules can occur.³ Above the point of obstruction the tubule may dilate widely, and this dilatation may extend the full length of the tubule proximal to the block. The degree of structural alteration depends largely on the state of the stroma, which by constriction may cause the formation of varices, outpouchings or stenosis of the hydronephrotic tubules. The blocking cast may so fill out the distal segment as to encroach on and deform surrounding structures. The proximal convoluted tubule placed in close proximity to the distal segment may then be flattened to a ribbon, and the glomerulus, attached to the macula densa of the distal segment, may also be badly misshapen. The glomerulus is never dilated

the hydronephrosis of tubular blockage. This has also been shown to be the case in the normal kidney deformed by hydronephrosis.³⁴

* * *

Several important facts, therefore, have emerged from the recent studies of renal pathology, especially those of Oliver, whose monograph³ should be consulted for further detail. First, the doctrine of glomerular dominance of the renal circulation is discredited by the finding of a gradual development of a predominantly tubular circulation through accessory vascular channels. Second, the role of the interstitial tissue in the renal deformation of chronic Bright's disease is reaffirmed and established. Third, hydronephrosis secondary to the obstruction of nephrons and collecting tubules is emphasized as contributing to the architectural deformity. Finally, the demonstration of hypertrophic units and of aglomerular tubules raises the question of the functional ability of these structures.

It seems reasonable to infer that hypertrophy and hyperplasia of renal structures indicate adaptive functional responses to increased demands resulting from a shrinkage in the total functional mass. Likewise, similar changes in aglomerular nephrons seem to indicate continued activity requiring secretion of water across the tubular epithelium. Since it is known that, in certain fish, aglomerular kidneys secrete urine, it has been suggested by Marshall³⁵ that a return to the more primitive state may occur in chronic renal disease. The demonstration of an increasing number of intact aglomerular nephrons in the kidney of Bright's disease³ appears to substantiate this hypothesis. Functional evidence of the operation of such aglomerular units, however, is totally lacking.

Initial Patterns of Disease

Although the fact that all forms of Bright's disease converge on a common terminal pattern requires emphasis, it should be remembered that each form of the disease has a distinctive initial pattern. In glomerulonephritis, glomerular damage dominates the earliest stage. Endothelial proliferation blocks the glomerular capillaries, and thrombosis and occlusion by crescent formation are occasionally observed. Thickening, fusion and splitting of the basement membrane are followed by the appearance of intracapillary fibers. A widespread interstitial inflammatory reaction, an irregular dilatation of proximal tubules and occasionally small deposits of lipid material in the tubular cells or in the vessel walls may be found. If healing occurs, these evidences of disease may be entirely removed, but if activity continues, the structural alteration usually becomes profound within one or two years. Oliver³ is of the opinion that two types of chronicity are manifest. In one, atrophy, hydronephrotic dilatation and disruption of tubules, and glomerular

obliteration are predominant; in the other, extensive tubular hypertrophy and hyperplasia with vascular readjustments occur. He attributes the former to a continuously active disease process, and the latter to remittent activity of the disease process, during which recuperation and compensatory renal changes take place.

In the nephrosclerotic kidney is found a very different pattern, consisting of arterial and arteriolar sclerosis and little interstitial inflammation. The small arterial branches are always the more severely involved, showing tortuosity and fatty deposits in the walls. Hyperplasia of the endothelium is frequently seen in small arteries and large arterioles and is usually "associated with medial degeneration (intracellular collagen and thinning) and in many instances complicated by hyaline, fat, mucoid or chromotropic degeneration, or necrosis of the hyperplastic intima as well as of the media."³⁷ Hyalinization of the afferent arteriolar intima often occurs. Interstitial fibrosis is evidenced at first by the formation of a few scars; later it is diffuse, with the destruction of the greater part of the cortical tissue. The tubules show atrophic changes within the scar and hypertrophy outside it. In the accelerated form of the disease (malignant nephrosclerosis), extensive and complete occlusion of the tubules and marked hydronephrotic changes are widespread. In addition, variable changes in any one nephron, such as hypertrophy and atrophy, are of common occurrence. Necrosis of the wall of the afferent arteriole may be found, with contiguous inflammation of the surrounding interstitium.²⁷

The nephrotic kidney shows relatively little change in its architecture, even though numerous casts may fill the tubules and disruption may occur. Depending on the etiology a heavy lipoidal deposit in the tubular epithelium may be found.

In acute pyelonephritis, focal accumulations of polymorphonuclear leukocytes appear throughout the kidney, about venules and capillaries plugged by bacterial emboli or about glomeruli.^{25, 26} These accumulations may develop into multiple abscesses destroying and replacing local structures. Following release of the obstruction to urine flow in the experimental animal, and possibly in man, regression occurs, the lesions are resolved and a diffuse interstitial fibrosis sets in, which damages nephric units not previously affected by the disease.

Terminus and Differential Diagnosis

It is not unusual for renal disease to become clinically manifest only when the kidney fails, and it is precisely at this stage that differential diagnosis is particularly difficult because few distinctive pathological or clinical features may stand out. Since the processes involved in the disorganization of renal structure are common to all types of Bright's disease, it is not surprising that convergence from initially specific patterns on a terminal similarity

of structure and function occurs. Mansfield, Mallory and Ellis³⁸ have considered this problem in 59 patients dying in uremia at the Boston City Hospital in whom the diagnosis was made on pathological grounds. In these cases no pathognomonic pattern of clinical or laboratory findings could be discerned. It was thought, however, that a diagnosis should be attempted although frequently it could be reliably based only on a knowledge of the natural history of the disease. In many cases this information may be lacking and diagnosis must be tentative. Pathological diagnosis is usually less difficult but even then differentiation may be controversial. These facts are evident in the confusion in the literature regarding pathological differentiation of chronic and healed pyelonephritis from the other forms of chronic Bright's disease. Mansfield and his co-workers³⁸ quote unpublished data of Kinney and Mallory as indicating evidence of healed pyelonephritis in almost 14 per cent of all autopsies. On the contrary, Shure³⁹ found pyelonephritis in only 2.44 per cent (290 cases) of 11,898 post-mortem examinations and Bell²⁵ records an incidence of 2.47 per cent (808 cases) in 32,360 autopsies, of which only 64 cases were nonobstructive in origin. The great discrepancy in these figures can be attributed in part to a failure to establish uniform standards of diagnosis. Bell²⁵ and others^{40, 41} who have recently reviewed the literature reject pyelonephritis as an important cause of hypertension. Further studies are necessary to determine the relative importance of pyelonephritis and of chronic diffuse glomerulonephritis in causing renal failure.

(To be concluded)

CASE 30381

PRESENTATION OF CASE

A forty-nine-year-old housewife entered the hospital because of jaundice.

The patient was in apparent good health until about one and a half years before admission, when she had an attack of pain in the right upper quadrant radiating to the right shoulder blade. There was no jaundice. X-ray examination at a hospital in another city was said to be negative. About six months before entry she had another attack of pain in the right upper quadrant associated with slight fever and jaundice that lasted for one month. The stools were clay colored, and the urine was positive for urobilinogen. X-ray examination showed the gall bladder to be poorly visualized. The patient was well again until seven weeks before entry, when she became jaundiced and the stools were clay colored. She had pruritus but no pain until the week of admission, when she began to have intermittent pain in the right upper quadrant accompanied by discomfort in the right flank and some pain in the right scapula. She was seen by her physician who found urobilinogen in the urine and a normal galactose-tolerance test.

The past history was negative except for a history of herpes zoster about two years before entry.

Physical examination showed a well-developed and well-nourished, jaundiced woman. The heart and lungs were normal. The abdomen showed no spasm, tenderness or masses. Murphy's sign was absent.

The blood pressure was 170 systolic, 90 diastolic. The temperature, pulse and respirations were normal.

Examination of the blood showed a white-cell count of 13,400. The hemoglobin was 12 gm. per 100 cc. The urine was normal. The serum bilirubin was 12.1 mg. per 100 cc. direct, and 14.8 mg. indirect. The prothrombin time was 18 seconds (normal, 18 to 20 seconds).

The patient was given 4 mg. of hykinone twice a day intramuscularly and on the third hospital day an operation was performed.

*On leave of absence.

DIFFERENTIAL DIAGNOSIS

DR. LELAND S. MCKITTRICK: The late Dr. E. P. Richardson was credited with saying that one could make a diagnosis of gallstones in three minutes or one could not make it at all. I think he was right. I do not know what the diagnosis was in this patient. There is not evidence enough on this record, and I presume that the patient did not present evidence enough to make it possible for me to make a diagnosis that I am happy with. I should have liked to have a little more information from the patient, just to clear up one or two things in my own mind. I should have wanted to know more about the attack of pain one and a half years before entry. How severe was that pain? Was it a definite and severe enough attack so that it would have meant gallstones to me?

DR. BENJAMIN CASTLEMAN: The opening sentence in the original record reads, "The patient out of a clear sky had an attack of pain in the right upper quadrant, with radiation into the right flank and in the region of the right shoulder blade."

DR. MCKITTRICK: But we want to know whether she had to bend over, whether the pain was extremely severe, whether she walked the floor—those are little points on which one makes a diagnosis. Was she perfectly well between the attack of a year ago and the one six months ago and until the onset of the jaundice seven weeks ago? I should like to be more clear in my mind about these things. The attack certainly in location and distribution is typical of biliary colic. The second attack, with fever and jaundice, was apparently consistent with a stone in the common duct, and the third attack was not at all typical. Therefore, I cannot make a diagnosis that satisfies me. I shall start with that premise and take the case up from another point of view and see what I can do.

The first thing is to try to decide whether this was an intrahepatic or an extrahepatic jaundice. In other words, did this woman have a hepatitis of some type or another or some extrahepatic pathology, such as gallstones, stricture of a duct or carcinoma in relation to the duct or the head of the pancreas? I cannot even make that differentiation clearly. There are certain things that suggest one thing, and some another. The urobilinogen does not mean much to me. I believe that urobilinogen is not found in the urine in a straight case of obstructive jaundice, except in the early stages, when there may still be bile in the intestinal tract that may be absorbed. It is likelier to be found in the urine in cases of liver damage. Is that correct, Dr. Beckman?

DR. WILLIAM BECKMAN: Yes.

DR. MCKITTRICK: The normal galactose-tolerance test offers some evidence against severe intrahepatic disease. The prothrombin time was normal. There is some suggestion that if the patient did have

hepatitis she did not have extensive liver destruction. Seven weeks of complete absence of bile from the stools, I presume, is a reasonable length of time for the average case of hepatitis to go on. It may not be too long, but is long enough so that one should begin to feel uneasy about it.

This woman had two attacks of pain that I should try to link up with the final diagnosis, but I must confess that at this moment I am not sure that I can do it in a logical manner. I am certain that the important decision to make is whether the patient had a surgical or a medical jaundice. Could one make a diagnosis of intrahepatic disease with sufficient accuracy to say that the patient should not have been operated on? That I cannot do. I believe that it was a surgical jaundice, not because I have strong conviction that it could not have been intrahepatic, but because she had two previous attacks of pain and for seven weeks had acholic stools. Having decided in my own mind that the patient should have been operated on, I should try to clarify in my mind — and the family also would have liked to know — what I thought that I was operating for, whether for gallstones or a carcinoma of the duct or the head of the pancreas.

This patient had had two previous attacks of pain. When a patient has had two such attacks, it seems to me that the question of gallstones cannot be excluded; no matter what the rest of the picture indicates. This patient did not present the classic picture of carcinomatous obstruction to the common duct, that is, the triad on which I place a great deal of importance — progressive and painless jaundice and a palpable gall bladder. The jaundice had progressed for seven weeks, and there was no pain at the onset of the jaundice, but the gall bladder was not palpable.

What about gallstones? Could gallstones give an attack of jaundice without pain? Of course they can. The mere fact that she had had two previous attacks of pain, one of which was associated with jaundice, is considerable evidence in support of the possibility that gallstones were present. On the other hand I think I am correct in saying that we do not see many women forty-nine years of age with a gallstone history dating back only one and a half years, during which time they have had only two attacks, in whom an attack due to a common-duct stone is initiated with painless jaundice. The biliary setup that usually gives painless jaundice is the contracted gall bladder where the stone has been squeezed down into the common duct and has settled down in the ampulla. This particular setup generally occurs in cases with long-standing biliary-tract disease and is infrequent.

It seems to me that we are left trying to put together from this bit of confusing evidence a reasonable diagnosis. I believe, although I have no strong conviction about it, that this jaundice was of extrahepatic origin. I must make a diagnosis of gall-

stones, although I am not happy about it. If I had talked with this patient, I believe that I should have found out something about these attacks of pain that would have clarified them in my mind. All I have to go on is the location, the sudden onset and the radiation. In the presence of a story of this sort I must make a diagnosis of gallstones.

Then the question comes up, If gallstones were present, were they the cause of the most recent attack? The mere fact that she had gallstones does not mean that she was being operated on for a condition secondary to the presence of such stones. Six months is a long time to go between attacks due to a stone in the common duct. Usually the attacks become more and more frequent as the stone gets into the common duct.

I could talk the rest of the day and not be any nearer to a definite diagnosis. I had better stop. I think, without conviction, that this was an extrahepatic condition. I will make a diagnosis of gallstones but I am not sure whether the obstruction to the cause of the jaundice, was a stone in the common duct or carcinoma related to the ductal system or possibly to the head of the pancreas. So long as one has to put one diagnosis in front of the other and rather than make two diagnoses, I will say that I favor a diagnosis of gallstones, with a stone impacted in the ampulla.

DR. MAURICE FREMONT-SMITH: The fact that she had one episode of jaundice and clay-colored stools, without pain, is additional argument for a stone, is it not?

DR. MCKITTRICK: It is a good logical course of events, but on the other hand, it is so good that I am suspicious. I am a little upset by the long interval — six months — between the second attack of pain and the development of painless jaundice.

DR. LLOYD MILLS: Regarding painless, progressive jaundice, a recent statistical survey of carcinoma of the head of the pancreas indicates that over 50 per cent of the patients had pain at some time during the course of the disease and that a smaller percentage had intermittent rather than progressive jaundice.

DR. MCKITTRICK: I shall answer that in a different way. Whenever there are variations, one has to be careful of conclusions. When one has a patient, however, who says that the family noticed that her eyes were yellow and she becomes more and more jaundiced, that jaundice was not initiated with an attack of pain — in other words, the jaundice was painless. If these two things happen and one can palpate a large smooth gall bladder, they nearly always mean a malignant obstruction to the common bile duct.

CLINICAL DIAGNOSES

Chronic cholecystitis.
Cholelithiasis?

DR. MCKITTRICK'S DIAGNOSES

CASE 30382

Cholelithiasis.
 Choledocholithiasis?
 Carcinoma of common bile duct or head of pancreas?

ANATOMICAL DIAGNOSES

Adenocarcinoma of right hepatic duct, with extension into the entire common duct.
 Cholelithiasis.
 Chronic cholecystitis.

PATHOLOGICAL DISCUSSION

DR. CASTLEMAN: At operation the surgeon removed a thickened distended gall bladder; the right and left hepatic ducts and the common duct were markedly distended, being two or three times the normal diameter. After the cystic duct was clamped and compressed in such a manner as to force its contents into the common duct, the common duct was opened and a cast of the duct composed of greenish-black, rubbery, tissue-like material was pulled from the entire common duct. Similar material was suctioned from both hepatic ducts. I was called to the operating room and shown this material. The outside was coal black, but the inside was a mottled pinkish red and looked like definite tissue. A frozen section proved it to be an adenocarcinoma. The surgeon was able to scoop out this material easily because it was not adherent. The origin of the tumor was believed to be in the right hepatic duct, because its wall was thicker and rougher than the rest of the duct. There were no definite stones in the common duct, but the gall bladder had small blackish stones. I suppose that stones had been passing through the common duct for some time. A T-tube was placed in the common duct.

DR. MCKITTRICK: Was the ampulla patent?

DR. CASTLEMAN: Yes.

DR. LAURENCE L. ROBBINS: A postoperative cholangiogram shows a constant defect in the right hepatic duct.

DR. MCKITTRICK: That makes a perfectly good story. She could have had a hemorrhage from the tumor, and the blood could have passed down and caused an attack of pain the same as that of gallstones. The only reason that one says gallstones is that there is not much else in the biliary tree, except gallstones, to give attacks of pain. The last attack of jaundice can be explained by the propagation of this tumor mass down the common duct and gradual occlusion in that way.

DR. CASTLEMAN: Do you think anything more can be done surgically?

DR. MCKITTRICK: No; it is a difficult area to approach.

PRESENTATION OF CASE

A forty-seven-year-old married woman was admitted to the hospital in semicoma.

Because of the patient's stuporous state only a meager history was obtainable from relatives and her private physician. About five months prior to admission she first noted some rectal bleeding, which continued intermittently. The amount and color of the blood could not be ascertained. About six weeks before entry she developed lower abdominal pain, which became progressively severer and was associated with increasing constipation. For about four days prior to entry she was unable to move her bowels although she had a frequent and intense desire to do so. A physician was called and prescribed 0.02 gm. of pantopon every four hours. This regimen was followed religiously except when the patient slept. During the twenty-four hours before admission she became stuporous and ceased to void and during that time she received only 0.02 gm. of pantopon.

The patient had gonorrhea twenty years prior to admission and was treated for a year. About a year later she had an attack of redness and swelling of the knees and the joints of the feet, which cleared up after bed rest. Twelve years before entry she had attacks of vomiting and pain in the right upper quadrant, following which a cholecystectomy, choledochostomy and routine appendectomy were performed, with relief of symptoms. A few small stones were found in the gall bladder and one was removed from the common duct. At that time several urine examinations revealed a specific gravity ranging from 1.018 to 1.032, with no albumin and a sediment containing numerous white cells, occasional red cells and a rare cellular cast. For about ten years before admission she had had nocturia two to four times.

Physical examination revealed an obese woman in semicoma, breathing stertorously. She responded to shaking but not to painful stimuli. The pupils were very small, round, regular and equal, and there was only slight reaction to light. The mouth and tongue were dry. There was a uriferous odor to the breath, and a uremic frost was noted. The lungs were clear, and the heart, except for a rapid rate, was negative. The abdomen was moderately distended and there was slight tenderness to deep palpation in the lower portion. The deep tendon reflexes were active and equal, the abdominal reflexes were absent, and the Hoffmann and Babinski signs were positive. Pelvic examination revealed a prolapsed and lacerated cervix, but no masses could be felt in the vaults. Digital examination revealed a firm, rather smooth, fixed mass on the anterior wall of the rectum about 8 cm. above the anus; a small

amount of bright-red blood stained the examining finger.

The temperature was 98.6°F., the pulse 100, and the respirations 18. The blood pressure was 120 systolic, 75 diastolic.

Examination of the blood revealed a red-cell count of 4,000,000, with 70 per cent hemoglobin, and a white-cell count of 24,400, with 86 per cent neutrophils. A catheterized urine specimen had a specific gravity of 1.010, with an acid reaction, a +++ test for albumin and 10 white cells per high-power field; no sugar or acetone was present. The blood nonprotein nitrogen was 130 mg. per 100 cc., the serum protein 6 gm., and the chloride 89 milliequiv. per liter. A Hinton test was negative. Roentgenographic examination of the abdomen was unsatisfactory; it revealed considerable gas in the cecum and sigmoid, but no definite dilated loops of small bowel could be seen. An electrocardiogram was within normal limits. A biopsy of the rectal mass revealed adenocarcinoma.

Following admission the patient was catheterized and a considerable amount of pale urine was obtained. A lumbar puncture revealed clear fluid with normal dynamics. The respirations fell to 10 per minute, and she was treated with picrotoxin, receiving 14 mg. over a period of six hours, followed by inhalation of carbon dioxide. There was temporary improvement for several hours, but the respirations soon fell to their former level. On the third hospital day the ureters were catheterized. The catheters were passed with ease but no urine was obtained. Fluids were administered intravenously up to 2500 cc. daily, principally dextrose in water and some sodium lactate. By the fifth hospital day she had begun to void, her sensorium became clearer and her respirations had increased to 16 to 20 per minute. The ureteral catheters were then removed.

In spite of a fair urine output and apparent improvement enabling the patient to sit out of bed for short periods, the nonprotein nitrogen continued to rise, eventually reaching 235 mg. per 100 cc. The blood carbon dioxide content was 17.5 milliequiv. per liter. The blood pressure on several occasions reached 190 systolic, 110 diastolic, although it was usually lower. On the eighth hospital day a difference in the circumference of the two legs was noted. Homans's sign was negative. A prophylactic superficial ligation of a leg vein was done. On the following day the urine was red and cloudy, with a specific gravity of 1.010, an alkaline reaction, a +++ test for albumin and a sediment containing innumerable red cells and many white cells but no casts.

The patient's condition rapidly became worse. On the fourteenth hospital day she again became anuric and 25 per cent glucose and plasma were administered intravenously in a vain attempt to induce diuresis. The blood pressure fell to 120 systolic, 60 diastolic, and she vomited frequently. Gastric

lavage produced 750 cc. of bloody fluid, and she placed on constant gastric suction. She died on fifteenth hospital day.

DIFFERENTIAL DIAGNOSIS

DR. AUSTIN BRUES: In this case we are presented with a pathological diagnosis of adenocarcinoma apparently of rectal origin. This accounts well for the rectal bleeding and for the progressive constipation and abdominal pain. For the rest, it is necessary to establish the cause of the patient's anuria and death.

The first thought that naturally arises is that the terminal picture might have been due to extension of the malignant tumor. It is an interesting fact, however, that death by renal failure is a very common complication of cancer of the lower bowel, in contrast to cancer of the cervix and of the urinary tract itself. Metastasis from rectal carcinoma characteristically goes to lymph nodes and to the liver, the portal venous system, and spares the urogenital tract. We have no evidence to suggest that the pelvic tumor was large enough to compress the ureters, and finally, it is stated that catheters could be passed easily through both ureters. We are forced to conclude that the urinary suppression was of renal or prerenal origin.

What evidence do we have regarding the possibility that the patient had chronic renal disease? Twelve years before entry, at the time of the bladder operation, several urine examinations showed abnormal sedimentary findings, including red cells but no albumin. Also, for ten years before admission she had had nocturia. Unfortunately, we do not have a record of her blood pressure at any time prior to admission in coma, nor is there any examination of the eye grounds recorded. Either of these might have given us information whether this episode occurred in the course of chronic nephritis. Without them, we can only say that the history is suggestive of chronic renal disease which might or might not have been severe.

Assuming that the patient had indeed suffered from chronic glomerulonephritis or from chronic vascular disease with emphasis on renal impairment, what precipitated the present acute and fatal episode? Two possibilities stand out. This may, in the first place, have been an acute exacerbation of an acute hemorrhagic nephritis punctuating the course of chronic nephritis. It is perfectly possible, although not frequent, for acute nephritis to manifest itself by acute complete urinary suppression. In such a case the blood pressure would at first be normal, in the absence of chronic nephritis with hypertension, but this denies the first postulate, and we should have to minimize the chronic nephritis in favor of acute nephritis *de novo*. Moreover, when urinary flow was obtained, the urine was at first clear. The hypothesis of acute nephritis with

without a previous renal background is not wholly satisfactory.

It seems to me that the case of a patient who is admitted in coma following dosage with pantopon, shows signs of morphine toxicity, and who at the same time develops fatal anuria, ought if possible to be explained on the basis of the drug. Sufficient doses of morphine depress blood pressure, and secondarily cause decrease or disappearance of urinary flow. The patient, however, had a normal blood pressure on admission. It is possible that she may have previously suffered from marked hypertension, although the clinical examination of the heart and the electrocardiogram do not suggest this, and that secretion of urine ceased when the blood pressure was brought down to a normal level, just as it may when the blood pressure of a normal person goes to shock levels. The second episode following vein ligation, on the other hand, being ushered in by hematuria without casts, suggests acute renal disease of some sort. Perhaps the previous ureteral instrumentation was responsible for the gross hematuria.

If this patient had received an earlier course of sulfonamide therapy, with dosage again just before admission, and perhaps again at the time of vein ligation, it would seem to me that this was a clear case of renal shutdown on a sulfonamide-sensitivity basis, and that we might expect to find inflammatory and granulomatous interstitial lesions in the kidneys. If she did get sulfonamides, however, this has been forgotten. Other drugs have occasionally been mentioned as factors causing anuria, and sensitization to opium derivatives, as evidenced by skin eruptions, does occur. Morphine has not to my knowledge been implicated in a picture such as this. We have nothing else in this case to suggest sensitization, such as skin rash, eosinophilia or fever. We do not even know for certain that morphine was given at the time of the vein ligation, although it probably was, the procedure being done under local anesthesia. The sequence of events and the lack of an entirely satisfactory diagnosis, however, tempt one to entertain such a thought.

Other causes of anuria, such as massive renal infarction, seem to have little to offer in this case. Extensive liver metastasis from rectal carcinoma might cause hepatic failure, with a high nonprotein nitrogen because of elevated amino nitrogen, and might interfere with the detoxication of morphine. I do not gather from the history that such unusually massive hepatic metastasis occurred, and we should still have to explain the anuria.

CLINICAL DIAGNOSES

Carcinoma of rectum.

Renal insufficiency, with uremia and anuria.

DR. BRUES'S DIAGNOSES

Adenocarcinoma of rectum.

Chronic and acute glomerulonephritis?

Acute interstitial renal disease, sensitization type?

ANATOMICAL DIAGNOSES

Acute pyelonephritis, with multiple small abscesses.

Chronic vascular nephritis.

Cardiac hypertrophy, hypertensive type, moderate.

(Uremia.)

Cystitis, acute and chronic.

Adenocarcinoma of rectum, with metastases to liver.

PATHOLOGICAL DISCUSSION

DR. BENJAMIN CASTLEMAN: The rectal carcinoma was located just below the rectosigmoid junction, and several small metastatic nodules were present in the liver. As Dr. Brues predicted, there were no metastases in the region of the ureters and no ureteral obstruction was apparent.

The kidneys together weighed 200 gm., the right a little heavier than the left. The capsules were thickened and adherent. The parenchyma was fairly soft, and the cortical and medullary markings were difficult to visualize. The cortex was somewhat narrowed and several yellowish-brown pin-point areas were present. Microscopically there was evidence of old vascular disease, especially of the arterioles, with hyalinization of a relatively small number of glomeruli. The remaining glomeruli appeared normal, and there was very little tubular atrophy or tubules filled with colloid casts, which should rule out chronic glomerulonephritis and chronic pyelonephritis, respectively, as the cause of the underlying renal disease. Superimposed on the chronic vascular nephritis was an acute pyelonephritis characterized by multiple small abscesses filled with bacteria, by pus in the tubules and by a fairly extensive polymorphonuclear infiltration of the parenchyma. The ureters were not dilated or thickened. The bladder was moderately inflamed.

The cause of the acute pyelonephritis is not easy to explain. So far as we know, the patient had not received any of the sulfonamides, and the purulent rather than granulomatous character of the inflammation is rather against a sensitivity reaction. Although the bladder was moderately inflamed, I believe that the infection was hematogenous rather than ascending from the lower urinary tract.

The heart weighed 410 gm. and showed left ventricular hypertrophy.

THREE SCORE AND TEN

THE longevity of the American people, the statisticians of the Metropolitan Life Insurance Company* tell us, reached its all-time peak in 1942. In that year white girl babies reaching their first birthday had, on an average, seventy years of life ahead of them, exceeding by one year the biblically allotted three score and ten. Not until their fortieth birthday did white males achieve an average expectancy of thirty additional years, thus suggesting, although by no means proving, that Methuselah was a lady.

*Statistical Bulletin. Metropolitan Life Insurance Company. Vol. 25, April, 1944. No. 4.

Actually, the figures of 1942 give us striking evidence of what improved living conditions have done for the race, since in that year the average length of life of all our people, white and colored, was practically sixty-five years, a gain of nearly sixteen years since 1900, when the average length of life was forty-nine years. The slow rise over earlier recorded expectations of life is, of course, a hundred-fold and more.

The ladies have always been better insurance risks than have the gentlemen, even in the lush years of peace and plenty. Since the turn of the century, for instance, the distaff side of the family has been granted an average increase in length of life of over seventeen years, as compared with the fifteen years accorded to the sterner sex; and even at the age of forty the remaining years for females have increased nearly five years, as compared with the miserly two and a half years increase allotted to the breadwinners of the families.

Among our colored population a noticeable improvement in life expectancy has also taken place, with an increase of nearly twenty-two years for males, and twenty-three years for females. But this substantial advance only brings the colored population up to a 1942 life expectancy of fifty-four years for males, and fifty-eight years for females — about the expectancy that the white population of this country had already achieved some twenty years earlier.

These figures, even as we realize that they are brought about largely by reductions in infant mortality and in the mortality of childhood, put a different and a more benign emphasis on the possibilities of a pleasant old age. The average person of sixty-five, for example, now faces the prospect of thirteen more or less pleasant years ahead and may even reach the age of eighty or more, if his health is above the average.

Some falling off in this expectation has taken place in 1943 and will continue in 1944 — years of stress and strain and overwork, and moreover years in which a minor epidemic of respiratory infections exacted an increased toll of lives. The future, however, if we consolidate our gains, holds out an increasingly pleasing prospect.

PNEUMONIA IN SHIPBUILDERS

THE recent tremendous addition to the number of welders engaged in essential war industries has brought into focus the possibility of an increase in respiratory diseases in such workers resulting from the character of their tasks. Symptoms of various sorts are attributed by these workers and by many physicians to the fumes to which they are exposed. The symptoms may simulate those of acute systemic or respiratory infections or those of chronic respiratory diseases. The former are encountered most frequently during the season when acute respiratory infections have the greatest incidence, which suggests an increased susceptibility of such workers to the prevalent infections. The latter are usually recognized in x-ray films of the chest taken routinely or because of respiratory symptoms.

With respect to the lung changes in electric-arc welders, Sander¹ has recently pointed out the importance of preventive measures for the protection of workers. He finds that electric-arc welding that is done in large rooms, or where the fumes are not allowed to concentrate excessively near the breathing level, does not cause lung changes even after many years of work. On the other hand, excessive inhalation of concentrated fumes, especially in confined and unventilated spaces, may cause siderosis. The siderosis so produced consists of the deposit of inert iron pigment in the lymphatics without fibrous-tissue proliferation and without progressive changes after the exposure is materially decreased. Sander also states that welding and siderosis do not predispose to tuberculosis or to other lung infections, nor do they cause functional impairment of the lungs or symptoms referable to the lungs. Acute irritations of the throat, however, may occur with too prolonged work in dense clouds of fumes, but these appear to be transitory and to leave no residual. He believes that any respiratory involvement may be prevented in welding, even with the most prolonged and confined work, if proper precautions are taken by installing adequate exhaust ventilation and by using ventilated helmets or positive-pressure respirators.

Another study, carried out by physicians of the Permanente Foundation Hospital² among the workers of the Kaiser Richmond Shipyards on the West

Coast, suggests that acute pulmonary infections are neither more frequent nor more serious among shipbuilders than among similar persons in other walks of life. This study covered a twelve-month period during which 864 patients with pneumonia were treated. Some of the findings and the conclusions based on this study are worth mentioning.

The annual frequency rate of pneumonia at the shipyards was 9.5 per 1000 workers. This is probably a high incidence, but, as the authors point out, there are no reliable data to indicate that it is any different in shipyard workers than among the general population. It certainly is lower than the rate among certain types of workers in the iron and steel industries, but it is higher than the average incidence reported for all iron and steel workers.³

The type of pneumonia among the shipyard workers was in no way different from that among the general population. There was no indication that workers who had recently migrated to the region of the shipyards from other states were more susceptible to pneumonia than those who had lived in that region for a long time. The incidence rate for pneumonia was independent of the length of employment at the yards, as well as of the type of work done by the workers. In particular, pneumonia was no more frequent among welders than among those doing other jobs, such as laborers, electricians and machinists.

The gross mortality for the entire group of patients with pneumonia was 8.2 per cent. This figure, as the authors point out, compares favorably with that achieved in many of the best clinics throughout the country. A large proportion of the patients were over forty years of age and had more than one lobe involved. The mortality in patients under forty years of age was less than 4 per cent, and in those having only a single lobe involved it was less than 5 per cent. These low fatality rates suggest that the conditions to which the shipyard workers were exposed did not aggravate the prognosis in those who acquired pneumonia. More likely, however, it reflects the fine type of medical care that these patients received.⁴

Apparently the United States Maritime Commission has been deeply concerned about the widespread rumors among workers and physicians that

welding causes respiratory disease. The commission is, therefore, anxious to give the findings among the Kaiser shipyard workers widespread publicity in order not to discourage people interested in this form of employment.

MASSACHUSETTS MEDICAL SOCIETY

STATED MEETING OF THE COUNCIL

A stated meeting of the Council of the Massachusetts Medical Society will be held in John Ware Hall, Boston Medical Library, 8 Fenway, Boston, on Wednesday, October 4, 1944, at 10:00 a.m.

Business:

1. Call to order at 10:00 a.m.
2. Presentation of record of meeting held May 22, 1944. (Published in the *New England Journal of Medicine*, issue of July 27, 1944.)
3. Reports of standing and special committees.
4. Appointment of an auditing committee.
5. Fill any vacancies in the offices of the Society.
6. Such other business as may lawfully come before this meeting.

MICHAEL A. TIGHE, M.D., Secretary

DEATH

CRAWFORD — Francis X. Crawford, M.D., of Dorchester, died August 19. He was in his seventy-second year.

Dr. Crawford received his degree from Harvard Medical School in 1898. He was a member of the staffs of St. Elizabeth's and the Carney hospitals and a member of the American Medical Association.

His widow and four sisters survive.

MASSACHUSETTS DEPARTMENT OF PUBLIC HEALTH

REIMMUNIZATION AGAINST TYPHOID FEVER

When a working basis for typhoid vaccination was established thirty-five years ago in the United States Army by Brigadier General (then Captain) F. F. Russell, the necessity for periodic reimmunization was recognized. At that time the policy of repeating the complete course of three doses of vaccine at three-year intervals was established. In recent years, the vaccination procedure as a whole has been extensively reinvestigated by the Typhoid Research Unit at the Army Medical Center. This group has found that adequate reimmunization can be obtained with a single dose instead of three doses of vaccine.

It is now well established that this single reimmunizing dose may be administered in one of two ways — 0.5 cc. subcutaneously or 0.1 cc. intradermally. Furthermore, it appears that this single dose is effective regardless of the interval since the last complete course of immunization.

The use of a single dose greatly simplifies the reimmunization process and also markedly reduces the incidence of local and systemic reactions, which are much more frequent and severe after reimmunization than during a first immunizing course.

The official recommendations are as follows:

- (1) The administration of full courses of typhoid vaccine to persons who have previously been immunized against typhoid fever is unnecessary and should be abandoned.
- (2) Wherever renewal of immunity is indicated in a previously vaccinated person, a single dose of vaccine should be administered.
- (3) This dose should consist of 0.5 cc. subcutaneously or 0.1 cc. intradermally. Although there is evidence that intradermal injections are somewhat more effective than those given subcutaneously, it should be noted that the smaller dose is probably ineffective if it happens to be given subcutaneously instead of intradermally.
- (4) The ideal interval between successive typhoid immunizations is one year, but a lapse of time greater than this between successive immunizations does not necessitate the administration of a full three-dose course of inoculations.
- (5) Whenever there is doubt concerning the best immunization procedure to follow, it is suggested that the physician in charge consult one of the persons given below regarding the performance of a protection test on the patient's serum. This test, which can be done in four or five days at the Antitoxin and Vaccine Laboratory, is considered the best available method of determining a patient's immunity status.

*Made reportable December, 1943.

†Pfeiffer-bacillus meningitis only other form reportable previous to 1941.

COMMENT

Anterior poliomyelitis, although showing a definite increase over the same period in 1943, does not indicate that epidemic proportions may be reached. It is impossible at this time to determine what the trend will be in the months ahead.

Mumps has shown an increase of almost 50 per cent over the corresponding period last year.

Dysentery has shown the usual seasonal increase.

Malaria has shown an increase, but the increase is primarily due to the return of service men from foreign fields.

The usual seasonal decline is noted in several of the diseases.

GEOGRAPHICAL DISTRIBUTION OF CERTAIN DISEASES

Actinomycosis was reported from: Burlington, 1; total, 1.
Anterior poliomyelitis was reported from: Ayer, 1; Boston, 2; Camp Myles Standish, 1; East Longmeadow, 1; Hinsdale, 1; North Adams, 1; Pittsfield, 3; Quincy, 1; Springfield, 5; West Springfield, 6; Winchester, 1; total, 23.

Diphtheria was reported from: Boston, 4; Brookline, 1; Cambridge, 1; Lawrence, 1; Methuen, 3; New Bedford, 1; Revere, 1; Somerville, 1; Taunton, 1; total, 14.

Dysentery, bacillary, was reported from: Worcester, 11; Wrentham, 12; total, 23.

Hookworm disease was reported from: Framingham, 1; total, 1.

Malaria was reported from: Ashland, 1; Cambridge, 1; Camp Edwards, 11; Cushing General Hospital, 22; Fort Devens, 20; Gloucester, 1; Hanson, 1; Lynn, 1; Medford, 1; Milford, 1; Quincy, 1; Reading, 1; Somerville, 1; Springfield, 1; Waltham, 1; Winchester, 1; total, 66.

Meningitis, meningococcal, was reported from: Boston, 6; Braintree, 1; Chelsea, 1; Everett, 1; Fairhaven, 1; Grafton, 1; Haverhill, 1; Lowell, 2; Lynnfield, 1; Malden, 1; Melrose, 1; Methuen, 1; New Bedford, 1; Newton, 1; Pittsfield, 2; Quincy, 1; Revere, 1; Salem, 1; Saugus, 1; Shrewsbury, 1; Spencer, 1; Springfield, 2; Webster, 1; Worcester, 1; total, 32.

Meningitis, Pfeiffer-bacillus, was reported from: Tisbury, 1; total, 1.

Meningitis, pneumococcal, was reported from: Boston, 1; Dartmouth, 1; total, 2.

Meningitis, streptococcal, was reported from: Adams, 1; Barnstable, 1; Orleans, 1; Springfield, 1; total, 4.

Meningitis, other forms, was reported from: Cambridge, 1; total, 1.

Meningitis, undetermined, was reported from: Millbury, 1; total, 1.

Salmonella infections were reported from: Cambridge, 1; Dedham, 1; Lawrence, 1; Malden, 1; Methuen, 1; Salem, 2; Somerville, 1; Waltham, 1; Worcester, 2; total, 11.

Septic sore throat was reported from: Boston, 3; North Adams, 1; Quincy, 1; total, 5.

Tetanus was reported from: Springfield, 1; total, 1.

Trichinosis was reported from: Marblehead, 1; Norwood, 1; total, 2.

Typhoid fever was reported from: Boston, 1; Fall River, 1; total, 2.

Typhus fever was reported from: Boston, 1; total, 1.

Undulant fever was reported from: Boston, 1; Hatfield, 1; Middleboro, 1; total, 3.

CORRESPONDENCE

INVENTORY OF DEMEROL

To the Editor: A form letter has recently been sent to all narcotic registrants relative to the substance isonipicaine, commonly known as "Demerol," which by a recent act of Congress has been brought under the provisions of the federal narcotic laws.

All registrants were called on to file an inventory with the Collector, not later than September 1, of Demerol on hand as of July 1. Many are under the impression that no inventory was required if they had no Demerol to report. This is not correct. In cases where registrants have no Demerol on hand, their inventory should so state. Those who failed to file on the required date should do so immediately.

The original sworn copy is to be sent in to the Collector, and the duplicate retained.

DENIS W. DELANEY, *Collector*

Internal Revenue Service
Office of the Collector
Boston 9

CO-EXISTENCE OF GALLSTONES AND ULCER

To the Editor: In discussing one of the case records of the Massachusetts General Hospital (Case 30262) in the June 29 issue of the *Journal*, Dr. Wyman Richardson made the following statement: "The combination of gallstones and ulcer in the same patient is almost unheard of. . . . It is a striking thing that the ulcer habitus and the gallstone habitus are quite different, and I do not believe that I have ever seen the two diseases in the same patient." Since these cases are widely read, frequently quoted and generally considered authoritative, I believe the above quotation should be challenged.

Many years ago the Drs. Mayo emphasized an abdominal triad — appendicitis, gall-bladder disease and ulcer — in the same patient.

In 1931, Dr. Franklin W. White and I (*New Eng. J. Med.* 205:793-797, 1931) reported a case of gastric ulcer and gallstones. Therein we stated, "The presence of gallstones naturally does not exclude ulcer; both may be present, in fact the association of lesions in the duodenum or stomach and the gall bladder is not at all rare." I am still subscribing to this view on the basis of my own experience and that of many others.

In 1943, Dr. S. A. Robins and I (*Am. J. Digest Dis. & Nutrition* 10:445-447, 1943) quoted 3 patients who had had subtotal gastrectomy for intractable ulcers and later developed gallstones. I can also recall at least 2 patients who were operated for gallstones and showed at the accompanying exploration of the abdomen an active ulcer in the duodenum.

The day after I read the discussion of the above case I saw a patient who gave a twenty-year history of an ulcer. A duodenal ulcer was demonstrated by x-ray study in 1938 and again in 1944, and at the latter examination two large gallstones were also shown.

I have seen both in private and in hospital practice other cases in which a peptic ulcer and gall-bladder disease were present in the same patient. I have no records on hand to substantiate these cases, but I do not believe that it is necessary in view of the above facts.

I. R. JANKELSON, M.D.

BOOKS RECEIVED

The receipt of the following books is acknowledged, and this listing must be regarded as a sufficient return for the courtesy of the sender. Books that appear to be of particular interest will be reviewed as space permits. Additional information in regard to all listed books will be gladly furnished on request.

Medical Parasitology: A laboratory manual. By Jacques Yetwin, M.S., M.D., medical technologist and associate professor of parasitology, Middlesex University School of Medicine, Waltham, Massachusetts. Fourth edition. 8°, cloth, 126 pp., with 127 illustrations. Boston: Boston Linotype Print, Incorporated, 1944. \$3.00.

This manual of a laboratory course has been modified to suit existing conditions brought on by the present war. The time allotted to the course has been increased from sixty to seventy-five hours. Mycology, as a rule, has been omitted, since it is taught in the course on bacteriology. The illustrations have been taken from a collection of five hundred slides of important parasites.

Baby Doctor. By Isaac A. Abt, M.D. 8°, cloth, 310 pp. New York: Whittlesey House, 1944. \$2.50.

This autobiography of an eminent pediatrician who has practiced his specialty for fifty years naturally reflects the history and advances in pediatrics during that period.

Health and Hygiene: A comprehensive study of disease prevention and health promotion. By Lloyd Ackerman, Ph.D., Western Reserve University. 8°, cloth, 895 pp., with 59 illustrations and 27 tables. Lancaster, Pennsylvania: The Jaques Cattell Press, 1943. \$5.00.

This popular treatise on health is based on the latest information and includes thorough discussions of nutrition, sex, infection, inflammation, immunology, mental attitudes and behavior problems. The first three parts are historical. The work is well written and printed with a good type on good paper.

The Hospital in Modern Society. Edited by Arthur C. Bachmeyer, M.D., director, University of Chicago Clinics, and director, Hospital Administration Course, University of Chicago; and Gerhard Hartman, Ph.D., director, Newton Hospital, Newton Lower Falls, Massachusetts. 8°, cloth, 766 pp., with 3 illustrations and 5 tables. New York: The Commonwealth Fund, 1943. \$5.00.

In this compact volume will be found a collection of readings selected from the literature in the hospital field and in the allied fields of medicine, public health, management and organization, law, sociology and psychology, comprising the essence of the published material on hospital administration. The work is intended for individuals interested in all aspects of hospital administration, and although not exhaustive, it represents an endeavor to assemble material that is so widely dispersed in the literature that it is unavailable to the average reader.

Gastro-Enterology (in three volumes). By Henry L. Bockus, M.D., professor of gastroenterology, University of Pennsylvania Graduate School of Medicine; and colleagues at the University of Pennsylvania Graduate School of Medicine. Volume II. *The Small and Large Intestine and Peritoneum: Diagnosis and treatment of disorders of the small intestine, colon, peritoneum, mesentery and omentum.* 4°, cloth, 975 pp., with 311 illustrations and 53 tables. Philadelphia and London: W. B. Saunders Company, 1944. \$12.00.

This second volume of a complete treatise of the gastrointestinal tract has been published on time despite the great difficulty encountered during the present war. It is hoped that the third volume on the liver, biliary tract and pancreas may be published as promptly.

NOTICES

SUFFOLK CENSORS' MEETING

The censors of the Suffolk District Medical Society will meet for the examination of candidates at the Boston Medical Library, 8 Fenway, Boston, on Thursday, December 7, at 4:00 p.m.

FELLOWSHIPS IN CHILD PSYCHIATRY

A limited number of fellowships are being offered for training in extramural child psychiatry. Selection for these fellowships is made by the National Committee for Mental Hygiene following the recommendation of eligible applicants for appointment. These fellows will spend one or two years in a selected clinic, the term and plan of the fellowship to be determined by the peculiar needs of the applicant. The training is pursued according to a definite plan related to the probable future functions of these fellows. Candidates for fellowship award should have had at least a general internship and two years devoted to psychiatry in an approved mental-hospital service, in addition to other qualities fitting them for extramural service. Since this provision of training fellowships comes in response to a definite paucity of personnel in this field, peculiarities of the demand are considered in making appointments. The stipends vary slightly with location and status of the fellow but in general range between \$2000 and \$2400.

Requests for further information about these fellowships, and applications therefor, should be addressed to Dr. Milton E. Kirkpatrick, National Committee for Mental Hygiene, 1790 Broadway, New York 19, New York.

PUBLIC HEALTH CONFERENCE

The Second Wartime Public Health Conference will be held in the Hotel Pennsylvania, New York City, on October 2, 3, 4 and 5.

Thirteen organizations will co-ordinate their own conferences, demonstrations and symposiums with the seventy-third annual business meeting of the American Public Health Association in discussion and evaluation of all phases of public-health protection that will have far-reaching effects in the postwar world.

New global frontiers in public health will be reported by some of the pioneers who helped establish them. New diseases encountered by American armed forces in various parts of the world, insect problems, control measures against importation of disease by returning veterans and new disinfectants are among the things that will be discussed.

From the civilian front will come reports on sanitary engineering, laboratory technic, milk control, dental care, social and industrial hygiene, school health, public-health nursing, wartime nutrition, wartime food and drug adulteration, air-borne infections and various other diseases.

More than three hundred health officials will read papers or participate in panel discussions. The organizations meeting jointly with the American Public Health Association are as follows: American Association of Public Health Dentists, American Film Center, American School Health Association, American Social Hygiene Association, Industrial Nursing Consultants, Municipal Public Health Engineers, Reciprocal Sanitary Milk Control, State and Provincial Public Health Laboratory Directors, State Directors of Public Health Education, State Directors of Public Health Nursing, State Sanitary Engineers, Teachers of Preventive Medicine and National Publicity Council for Health and Welfare Services.

AMERICAN BOARD OF INTERNAL MEDICINE

The next written examination of the American Board of Internal Medicine will be held on February 19, 1945. The closing date for the acceptance of applications is December 15, 1944.

SOCIETY MEETINGS AND CONFERENCES

CALENDAR OF BOSTON DISTRICT FOR THE WEEK BEGINNING THURSDAY, SEPTEMBER 28

SATURDAY, SEPTEMBER 30

*10.00-11:30 a.m. Medical staff rounds. Peter Bent Brigham Hospital.

MONDAY, OCTOBER 2

*12:15-1:15 p.m. Clinicopathological conference. Peter Bent Brigham Hospital.

TUESDAY, OCTOBER 3

*12:15-1:15 p.m. Clinicoröntgenological conference. Peter Bent Brigham Hospital.

WEDNESDAY, OCTOBER 4

Medicolegal conference, Mallory Institute of Pathology, Boston.

*12.00 m. Clinicopathological conference. Children's Hospital.

*Open to the medical profession.

ABNORMAL CARBOHYDRATE METABOLISM IN HUMAN THERMAL BURNS*

Preliminary Observations

F. H. L. TAYLOR, PH.D.,† STANLEY M. LEVENSON, M.D.,‡ AND MARGARET A. ADAMS, A.B.§

BOSTON

UNTIL the last few years shock has been apparently the major cause of death in the first few days following severe burns. It is now well established that it can be prevented or successfully treated in most patients if they are seen soon enough after thermal injury. There are, however, still many early deaths among severely burned patients, despite the fact that clinical shock has not existed at any time or, if present, has been corrected. A series of investigations on the biochemical and physiologic changes occurring after thermal burns are being carried out with the view of determining the significance and therapeutic implications of these changes. The present communication is concerned with the preliminary observations on changes in carbohydrate metabolism and, to a lesser extent, with changes in nitrogen metabolism. Electrolyte studies carried out on these patients will be reported later.

Hyperglycemia occurring soon after burns has been reported in human beings by Davidson,¹ Underhill et al.,² Martin³ and McIver.⁴ In general, the rise in blood sugar was proportional to the severity of the burn. Many patients with minor burns showed no hyperglycemic response. The blood-sugar level in most cases returned to normal in twenty-four to forty-eight hours.

Lundberg and Backman⁵ and Slocum and Lightbody,⁶ working with burned rabbits, and Lambrecht, Driessens and Waremboorg,⁷ working with burned dogs, found similar results. The rise in blood sugar occurred within an hour after injury. The height and duration of the hyperglycemia was proportional to the severity of the burn. Thus, Lundberg and

Backman report that in first-degree burns the blood sugar may increase to a level as high as 172 mg. per 100 cc. thirty minutes after the burn: at the end of two hours the level was again normal. Animals with second-degree burns showed rises of the blood-sugar level as high as 215 mg. and it returned to normal at the end of seven hours. With third-degree burns, the level rose to 326 mg. and at the end of twenty-four hours the blood sugar was still at an elevated level (154 mg.).

Greenwald and Eliasberg⁸ reported hypoglycemia in 2 patients studied for the first time two and five days, respectively, following the burn injury. From their studies on burned rabbits they suggest that an early hyperglycemic phase is followed by a phase of hypoglycemia, but their data on this point are not convincing. Trusler et al.,⁹ working with fatally burned dogs, found low blood-sugar values twenty-four hours after burning. Earlier determinations were not done.

Thomsen¹⁰ and Wolff, Elkinton and Rhoads¹¹ have each reported 3 patients with moderately severe burns who showed impaired tolerance for glucose shortly after the injury. There was a gradual return to normal in the course of some days or even weeks.

The most recent study of carbohydrate metabolism following burning has been carried out by Clark and Rossiter.¹² Working with rabbits and rats, under ether anesthesia, these authors found an immediate rise in blood sugar after burning and a return to normal within twenty-four hours. The effect of the anesthetic was controlled. In rats, there was an increased blood lactic acid one hour but not three hours after burning. The blood lactic acid was not studied in rabbits. There was a slight decline in the carbon dioxide combining power in both rats and rabbits. In rats there was a fall in muscle glycogen but not in liver glycogen. In rabbits there was no change in liver glycogen in well-fed animals, but in animals starved for twenty-four hours there was a decrease. Muscle glycogen was not studied in rabbits. Liver slices from rab-

*From the Thorndike Memorial Laboratory, Second and Fourth Medical Services (Harvard) and the Burns Assignment of the Surgical Services, Boston City Hospital, and the Department of Medicine, Harvard Medical School

The work described in this paper was done in part under a contract recommended by the Committee on Medical Research between the Office of Scientific Research and Development and Harvard University. Presented, in part, before the meeting of the Subcommittee on Burns and Wound Infections, National Research Council, Washington, D. C., March 31, 1944

†Research associate in medicine, Harvard Medical School, chemist, Thorndike Memorial Laboratory, Boston City Hospital

‡Research associate in surgery, Boston City Hospital

§Laboratory assistant, Thorndike Memorial Laboratory, Boston City Hospital

bits showed an impaired ability to form glycogen from glucose, whereas glycogen breakdown by liver pulp was unchanged.

METHODS OF STUDY

The present report is based on studies of 35 consecutive patients with burns admitted to the Boston City Hospital during the last six months. There were no known diabetic patients in this group. The burns were treated locally with pressure dressings of dry sterile gauze, with no preliminary cleansing. Morphine sedation was given.

Samples of venous blood taken without stasis—usually from the femoral vein—were obtained on admission and at frequent intervals thereafter. The patients were admitted between one and two hours after the burn trauma. Any delay in admission beyond two hours is commented on in the appropriate place in the text.

Blood sugar was determined by two methods—one that of Folin,¹³ and the other a modified Benedict procedure^{14,15} following the removal of proteins by Somogyi's zinc sulfate method,¹⁶ the final dilutions being made in Rothberg Evans tubes.¹⁷ This second procedure greatly lessens the amount of non-glucose reducing substance in the filtrate, a matter of importance in determining "glucose" in the presence of hemoconcentration and hemolysis of red cells.¹⁸

A patient was presumed to have hyperglycemia when the Folin blood sugar exceeded 130 mg. per 100 cc., or the modified Benedict blood sugar 100 mg. Sugar tolerances were determined by the intravenous technic of Lozner et al.¹⁹ Insulin-tolerance tests were made by the intravenous injection of 0.1 unit of regular insulin for each kilogram of body weight. Lactic acid was determined by the method of Barker and Summerson,²⁰ and amino acids by the ninhydrin method of Van Slyke et al.^{21, 22} The carbon dioxide combining power, plasma proteins and chlorides were determined by the usual routine methods, as outlined by Peters and Van Slyke.²³ The serum sodium was determined by the method of Butler and Tuthill,²⁴ as modified by Consolazio and Dill.²⁵ Prothrombin times were determined by a modification²⁶ of Quick's²⁷ method. Cephalin flocculation tests were made by the method of Hanger.²⁸

Shock was evaluated by the usual clinical criteria of fall of blood pressure, high pulse rate, cold, clammy extremities and collapse.

Several patients were treated with therapeutic plasma from the Boston City Hospital Blood Bank. Since this plasma contains glucose in amounts varying from 10 to 17 gm. for each unit of 250 cc., it was necessary to control this factor. This was accomplished in two ways. First, in certain moderately burned patients plasma was withheld; second, other patients were treated with either glucose-free plasma obtained through the kindness of Captain L. R. Newhouser, of the National Naval

Medical Center, Washington, D. C., or glucose-free serum obtained by courtesy of Dr. Stephen Maddock, director of the Boston City Hospital Blood Bank. No protein, fat, carbohydrates or vitamins were given during the period of study, with exceptions that are specifically mentioned below.

RESULTS

Incidence of Hyperglycemia

The over-all admission picture on the 35 patients comprising this study is given in Table 1. Twenty-one patients were in a hyperglycemic state on entry. The initial Folin blood-sugar level varied from 132 to 352 mg. per 100 cc. One patient whose admission was delayed twelve hours had an initial level of 224 mg.

Hemoconcentration was present on admission in 14 patients, 13 of whom showed marked hyperglycemia. Of the 21 patients whose hematocrits were normal on entry, 10 showed a high blood-sugar level on admission. Although there was a close correlation between the incidence of hemoconcentration and that of hyperglycemia, fluctuations in the hematocrit were not, for the most part, paralleled by similar changes in the blood sugar, nor did the non-glucose reducing substances, as a rule, vary directly with the degree of hemoconcentration.

Six patients with burns involving 20 to 75 per cent of the body surface, chiefly of third degree, were admitted in clinical shock. All these patients showed hyperglycemia, the blood sugar ranging from 168 to 352 mg. per 100 cc.

The occurrence of hyperglycemia was directly related to the extent of the burn. Thus, of 9 patients admitted with 2 to 9 per cent of the body surface burned, 2 had hyperglycemia. Of 7 patients admitted with 10 to 19 per cent of the body surface burned, 4 showed marked increases in the blood sugar on admission. On the other hand, 19 patients had more than 20 per cent of the body surface burned, and of these 15 showed marked hyperglycemia.

There is an even more striking correlation of the initial hyperglycemia with the extent of third-degree burn. Sixteen patients were admitted with less than 10 per cent of the body involved with third-degree burns. Of these, 4 showed hyperglycemia, 1 of whom was admitted in shock. In contrast to this incidence, 17 of 19 patients who had third-degree burns on more than 10 per cent of the body surface showed an initial increase in blood sugar. The 2 patients in this group who are not classified as having hyperglycemia had blood-sugar levels at the extreme upper limits of normal.

The data show no correlation of hyperglycemia with previous nutritional status, age, sex or abnormalities in the body temperature on admission.

Duration of Hyperglycemia

The foregoing evidence demonstrates that hyperglycemia occurring shortly after injury is a characteristic finding in severely burned patients. The hyperglycemia persisted over a period of hours in all cases, and over a period of days in some. None of the patients studied showed a return of an

Carbon Dioxide Combining Power and Lactic Acid Level

Plasma carbon dioxide combining power and lactic acid determinations were made on 15 patients. The 4 patients with third-degree burns on less than 10 per cent of the body surface had plasma carbon dioxide combining powers above 20 millimol.

* Respiratory involvement

† Benedict blood sugar

elevated blood-sugar level to normal within twelve hours.

The effect of a moderately severe burn on the blood sugar is demonstrated by a study of the data of one patient (Fig. 1).

CASE 18 A 58-year-old woman, with a noncontributory past history, shortly before entry received flame burns on 15 per cent of the body surface, 10 per cent being third degree. The blood pressure and pulse were normal on entry and remained so during the first twenty-four hours. Plasma was withheld and 1500 cc of isotonic salt solution was administered intravenously, but no other parenteral fluids were given. The oral intake during the period of study was limited to water. The urine output was moderately reduced on the first day but became normal thereafter. The blood-sugar level on admission was 133 mg per 100 cc. Thereafter it rose, to a maximum of 238 mg. twenty hours after the burn. By that time the hematocrit, which had been normal on entry, had risen to a maximum of 51 per cent. Thereafter, both the hematocrit and the Folin blood sugar declined, the former reaching a normal value fifty hours after the injury. At that time, however, the blood-sugar level was 162 mg., and seventy-two hours after the burn was 141 mg.

per liter on entry and plasma lactic acid concentrations of between 2.8 and 3.3 milliequiv. per liter. Of the 11 patients with third-degree burns involving more than 10 per cent of the body surface, 6 had carbon dioxide combining powers below 20 millimol. per liter, the lowest value being 13.6 millimol. The lactic acid concentration was between 2.8 and 3.3 milliequiv. in 2 patients, between 4 and 5 milliequiv. in 2, and 6.5 milliequiv. in 8. Thus, as in the case of the initial hyperglycemia, there was a close correlation between the initial decrease in carbon dioxide combining power, lactacidemia and the extent of the third-degree burn.

The following case reports illustrate the course and duration of the changes in lactic acid level and carbon dioxide combining power.

CASE 2 The patient was a well-developed and well-nourished 33-year-old woman with a noncontributory past history who

1 hour before entry received flame burns on 30 per cent of the body surface. For the most part, the burns were deep second degree, only 2 per cent being third degree. The blood

FIGURE 1.

pressure, pulse, temperature and respirations were normal on entry and remained so during the period of study. During the first 24 hours she received 3000 cc. of isotonic salt solu-

tween 35 and 43 mg. during the first 39 hours and fell to 28 mg. at 63 hours.

The blood lactic acid level 2 hours after the burn was elevated to 2.8 milliequiv. per liter. During the next 6 hours it was within normal limits, but during the next 28 hours the concentration varied from 2.0 to 3.9 milliequiv. Further serial studies were not made, but a blood lactic acid determination on the 7th day was normal.

The carbon dioxide combining power of the plasma during the first 63 hours varied between 18 and 24 millimol. per liter. Thereafter, the values remained at 28 millimol. Therefore, during the early period following injury there was apparently a slight but definite decrease in the carbon dioxide combining power.

The blood-sugar level as determined by the Folin method was normal on entry and as determined by the Somogyi-Benedict method was slightly elevated. It gradually rose, the maximum hyperglycemia being observed at 8 hours, with values of 197 mg. by the Folin method and 150 mg. by the Somogyi-Benedict method. The rise in the blood sugar and in the non-glucose reducing substances did not parallel the hematocrit. Thereafter there was a slow decline in the blood sugar over a period of 3 days. No glucose-tolerance tests were done on this patient until the 5th day after the injury, at which time the tolerance was normal.

CASE 13. The patient was a 50-year-old woman whose past history was noncontributory except for moderate alcoholic intake. She received flame burns of 10 per cent of the body surface shortly before entry. The entire burn was deep third degree, the injured skin being completely charred, with fat exposed in a number of places. The blood pressure, pulse and respirations were normal on entry and remained so during the period of study. Fifteen hundred cubic centimeters of physiologic salt solution was given by clysis, but no other parenteral fluids were given. The oral intake was restricted

FIGURE 2.

tion by clysis; plasma was withheld, and no other parenteral fluids were given. The oral intake of water and the urine output were low on the 1st day but normal in amount thereafter. The significant laboratory findings are presented in Figure 2.

The hematocrit, which was normal on entry, rose slowly during the first 19 hours, reaching a level of 56 per cent. From then on there was a slow decline to 41 per cent on the 3rd day, at about which level it remained. During that time the plasma protein concentration, which had been normal on entry, gradually fell 4.4 gm. per 100 cc. at the end of 39 hours, presumably owing to a shift of interstitial fluid into the blood stream. The nonprotein nitrogen fluctuated be-

to a small amount of water during the first 36 hours. The urine output was low the 1st day but normal thereafter. The data on this patient are given in Figure 3.

The hematocrit on entry was 44 per cent, at which level it remained for the first 14 hours. There was a slow decline to 34 per cent at the end of 3 days.

The plasma nonprotein nitrogen rose from a level that was initially normal to 75 mg. per 100 cc. 22 hours after the burn was sustained. It declined slowly and reached a level of 39 mg. 65 hours after the injury, at which level it remained. The plasma protein was 6.1 gm. per 100 cc. on entry and declined

slowly to 5.2 gm. in 3 days. On this basis, there was comparatively little interstitial fluid exchange in this patient.

Hyperglycemia, although present, was less marked than in Case 2. The blood sugar rose earlier and reached a peak

moderate and the nonprotein nitrogen remained normal, but a marked hyperglycemia, by both the Folin and the Somogyi-Benedict method, was present. The blood-sugar reached a level of 288 mg. per 100 cc. by the former method

FIGURE 3.

of 144 mg. per 100 cc. by the Folin method and 122 mg. by the Benedict method between 3 and 5 hours after the injury. The level thereafter was normal except for a transitory rise at 62 hours. A glucose-tolerance test done on the 4th day was normal.

In contrast to the relatively slight rise in blood sugar, there was soon after the injury a marked lactic acidemia. On entry, 1 hour after the burn, the blood lactic acid level was six times as high as the normal level, namely, 7 milliequiv. per liter. A high lactic acid level persisted for 14 hours, after which it slowly declined, reaching a relatively normal value in 62 hours.

The carbon dioxide combining power of the plasma, which was 21.4 millimol. per liter on admission, declined to 15.5 millimol. 12 hours later. Thereafter it slowly rose, reaching a level of 26.8 millimol. 62 hours after the burn.

The above two cases are typical of the findings in moderately burned patients, who, in our experience, usually recover from their injury. The following two cases represent patients who had much severer burns and who did not survive the injury.

CASE 14. The patient was a 42-year-old Negress who shortly before entry received flame burns when an oil stove exploded. No further history could be obtained. Physical examination on admission revealed a well-developed and well-nourished woman in moderate distress. The systolic blood pressure was 120, the pulse 90, and the respirations 20. After the burns were dressed it was not possible to take blood-pressure readings, but from the quality of the femoral pulse and the patient's general appearance it did not appear that any profound peripheral failure was present. She died 8 hours after injury from respiratory failure. Fifteen hundred cubic centimeters of plasma, containing about 75 gm. of glucose, was given in the period from 3 to 6 hours after entry. No other fluids were given parenterally or by mouth. There was marked hemoglobinemia. Five hundred cubic centimeters of clear urine was obtained on entry, but none thereafter. The rectal temperature varied from 102 to 102.8°F.

Three sets of observations were made and are summarized in Figure 4. The first two were made before any plasma or glucose had been given. Hemoconcentration was only

and of 241 mg. by the latter at the time of the last observations.

The carbon dioxide combining power of the plasma, which

FIGURE 4.

was 17.1 millimol. per liter on entry, fell to 12.5 millimol. in the next 4 hours.

The plasma lactic acid on entry was considerably elevated, a value of 9.4 milliequiv. per liter being obtained. During the next 4 hours the patient received a total of 80 cc. of 1.0 molar lactate and the lactic acid level rose to 12.5 milliequiv.

CASE 29. The patient was a 3-year-old Negress with a non-contributory past history who shortly before entry received third-degree flame burns on 70 per cent of the body surface, together with respiratory damage. Examination on entry revealed a well-developed and well-nourished child who was comatose, with labored respirations. The pulse was 160 and weak, and the extremities were cold and clammy. The clinical condition improved on the administration of oxygen and 600 cc. of plasma. The pulse became stronger and slower and the extremities warm. A Levine tube was passed into the stomach at the 2nd hour after the burn and bloody fluid was obtained. Small amounts of water were administered by gavage. On catheterization at the 5th hour 5 cc. of dark-red urine was obtained. The rectal temperature rose to 105°F. The respirations became more labored, and a tracheotomy was performed 3 hours after injury, with marked alleviation of the respiratory distress. Three hours later, however, the patient suddenly developed respiratory spasm and died.

The hemoglobin varied from 89 to 92 per cent, with the highest value 3 hours after the injury. (These values are higher than those usually found in children in this hospital and probably indicate hemoconcentration.)

The plasma nonprotein nitrogen on entry was 30 mg. per 100 cc. and by the 5th hour had risen to 89 mg.

The carbon dioxide combining power on entry was 13.6 millimol. per liter. During the next 4 hours, 50 gm. of glucose was given intravenously in divided doses. The blood sugar remained at a very high level, the highest value being 700 mg. per 100 cc. 2 hours after the last administration of glucose.

The blood lactic acid on entry was markedly elevated, being 7.2 milliequiv. per liter. Five hours after the burn injury it had risen to 12 milliequiv. No sodium lactate was administered.

Data with respect to glycosuria and acetonuria in the most severely burned patients are not available, owing to the scanty flow of urine during the period of study. Such evidence as is available indicates that there was no change in the renal threshold for glucose. Acetonuria was present in only 2 children, both of whom had normal blood-sugar levels but were moderately dehydrated. With correction of the dehydration the acetonuria disappeared.

Insulin Tolerance

Tolerance to insulin in the early hours following burn trauma was determined in 3 patients. The first patient, (Case 30) was a forty-five-year-old, known alcoholic addict who shortly before entry received a flame burn involving 20 per cent of the body surface, 15 per cent of the burn being third degree. Repeated cephalin flocculation tests were markedly positive, and at autopsy moderately advanced alcoholic cirrhosis was found. The insulin-tolerance test was begun 3 hours after injury, the blood-sugar level being 168 mg. per 100 cc. At that time the lactic acid was 6.6 milliequiv. per liter and the carbon dioxide combining power 19.2 millimol. The blood sugar fell to 108 mg. in one hour, and in two hours had returned to a value of 138 mg.

The other two patients had normal blood-sugar levels at the time the insulin-tolerance test was made. One of these (Case 31) was a seventy-five-

year-old man who had burns on 20 per cent of the body surface, chiefly deep second degree. During the test he showed mild transient shock. The lactic acid level and carbon dioxide combining power were essentially normal. The other patient, (Case 33) was a forty-two-year-old Negress with flame burns on 15 per cent of the body surface, chiefly third degree. The carbon dioxide combining power was also normal, but there was slight elevation of the lactic acid level (4 millimol. per liter). Both these patients showed marked insulin sensitivity five hours after injury. In the first, the control blood-sugar level was 97 mg. per 100 cc. One hour after the injection of insulin it had fallen to 66 mg., and at 2 hours it was still at the level of 60 mg. In the second patient the control blood-sugar level was 98 mg. per 100 cc. One hour after the injection of insulin it had fallen to 49 mg. and by two hours to 39 mg., and at three hours it was still at a low level (24 mg.) Repeated insulin-tolerance tests on the ninth and seventy-seventh days were essentially normal.

Glucose Tolerance

The interpretation of early glucose-tolerance tests in these patients is difficult because of the spontaneous changes in blood sugar. In some of the patients with hyperglycemia, however, it appeared that the added glucose was utilized; that is, the blood sugar two hours after the injection of glucose was the same as, or lower than, the control value. This is illustrated by the following three patients, one of whom was a well-nourished girl who was in good clinical condition at the time of the test. The second was a well-nourished young man in shock at the time of the test, and the third was an alcoholic addict with liver disease but without evidence of clinical shock.

CASE 25. The patient was a 12-year-old Negress with a noncontributory past history who shortly before entry received deep third-degree burns on 15 per cent of the body surface, an additional 5 per cent being involved in second-degree burns. Examination revealed a well-developed and well-nourished girl. The temperature, blood pressure, pulse and respirations were normal on admission. During the first 12 hours the patient received 750 cc. of glucose-free plasma and 360 cc. of water by mouth. There was no vomiting. The urine output was low. The blood pressure remained at about 120/80, the pulse was 110, and the general condition was good. The hematocrit rose from 41 to 47 per cent, whereas the plasma protein concentration remained at about 6.4 gm. per 100 cc. The plasma nonprotein nitrogen rose from 28 to 33 mg. per 100 cc. The carbon dioxide combining power of the plasma varied between 22 and 26 millimol. per liter. The lactic acid was elevated on entry, being 2.3 milliequiv. per liter, but fell to a normal value (0.8 milliequiv.) 12 hours after admission. The blood-sugar level on entry and again an hour later was 124 mg. per 100 cc. by the Somogyi-Benedict method. Twenty-five grams of glucose was injected intravenously at that time, and 2 hours later the blood-sugar level was still 124 mg. Thereafter it was normal. A glucose-tolerance test on the 3rd day was normal.

CASE 28. The patient was a 29-year-old man who received flame and electrical burns and some damage to the respiratory tract. Thirty-five per cent of the body was involved in second-degree and third-degree burns. On entry the blood

pressure was 130/70, the pulse was 100 and of good quality and the respirations were 25. The temperature during the first 5 hours was 103.6°F. Water in sips was the only fluid given. Plasma was withheld. During that time the patient gradually went into profound circulatory collapse, no blood pressure or pulse being obtainable for the last half-hour. There was no output of urine. The hematocrit rose to 72 per cent, and the plasma lactic acid concentration to 5 milliequiv. per liter. The blood-sugar level, which had been normal on admission, rose to 190 mg. per 100 cc. within 1 hour. A glucose-tolerance test was begun at that time. Two hours later the blood-sugar level was 157 mg.

CASE 27. The patient was a 38-year-old woman with probable liver disease who 1 hour before entry received third-degree flame burns on 50 per cent of the body surface. She was a known morphine and alcoholic addict. Physical examination revealed a well-developed and well-nourished woman. The blood pressure, pulse and respirations remained normal during the period of study. The plasma icteric index was 20 to 25 units. There was moderate hemoconcentration, lactacidemia and hyperglycemia. The carbon dioxide combining power varied between 18 and 20 millimeters per liter. A glucose-tolerance test was done at 4 hours. The control blood-sugar level was 286 mg. per 100 cc. Two hours after the injection of the glucose the level was 204 mg.

Glucose-tolerance tests on 4 patients after the fourth day were normal. Two of these patients had shown hyperglycemia, lactacidemia and lowered carbon dioxide combining power during the first two days, whereas the other patients had normal blood-sugar levels but had shown sensitivity to insulin.

Oxygen Consumption

Oxygen consumption was determined in 3 patients (Cases 28, 30 and 33) twelve to thirteen hours after injury. Calculated in terms of basal metabolic rates, the results varied from +34 to +58 per cent. The temperature in each case at the time of the determination was 103°F.

Icteric Index

In 23 patients the icteric indices were normal, whereas in 2 patients (Cases 27 and 30), both known alcoholic addicts, the index was elevated to 12 to 15 and 20 to 25 units, respectively. Of the remaining 10 patients, no data are available on 3; in the 7 others—all with burns involving more than 35 per cent of the body surface—the icteric index could not be estimated because of the presence of marked hemoglobinemia.

Cephalin-Flocculation Test

Serial cephalin-flocculation tests were made on 6 patients, all with third-degree burns involving more than 15 per cent of the body surface. In 3 patients (Cases 31, 32 and 33), the tests were negative, or at the most slightly positive (+). The icteric indices of these patients were normal. In the other 3 patients, 2 (Cases 30 and 34) of whom were known alcoholic addicts, and the third (Case 35) a poorly nourished man of eighty-three, the test was strongly positive (+++ to ++++++) throughout their courses. In two of these patients the icteric indices were not determined because of the presence of hemoglobinemia. In the third patient it was elevated to 15 units.

Prothrombin Time

Serial prothrombin determinations were made on the same 6 patients in whom the cephalin flocculation was studied. Of the 3 with negative cephalin-flocculation tests, 2 (Cases 31 and 33) showed normal prothrombin concentrations and 1 (Case 32) showed slight prolongation eighteen hours after the burn. Of the 3 with positive cephalin-flocculation tests, 2 (Cases 30 and 34) showed moderate prolongation four and forty-one hours, respectively, after the burn.

DISCUSSION

From the data presented it is clear that hyperglycemia, lactacidemia and lowered carbon dioxide combining power are frequently found in human subjects following thermal injury. The extent and duration of the changes in these blood constituents are roughly proportional to the severity of the burn. Muscle and liver glycogen determinations were not made in these patients; however, Clark and Rossiter,¹² working with rats, and Greenwald and Eliasberg,⁸ working with rabbits, found decreases in the muscle glycogen following burns. Clark and Rossiter found no change in liver glycogen in rats and rabbits previously well fed, whereas in rabbits previously starved there was a decrease. Following burn injury, there was no significant degree of early liver damage in those patients treated with simple dressings who came to autopsy in this hospital. The few patients who showed clinical and laboratory evidence of liver damage had a long history of alcoholism and doubtless had liver damage previous to the burn. In 1 patient with such presumptive evidence, the liver was found at autopsy to be markedly cirrhotic. It appears, therefore, that in the presence of a normal liver any increase in lactic acid production due to an increase in the rate of muscle glycogenolysis may result in hyperglycemia. The rate of lactic acid formation following burns is, however, apparently greater than the liver can handle, resulting in lactacidemia as well as hyperglycemia.

In addition to an increased glycogenolysis, another possible source of the extra blood sugar is glucogenesis from protein. It has been shown that following thermal burns there is an early increase in protein catabolism, with the excretion of excessive amounts of nitrogen in the urine.²⁹ It is quite possible that some of this protein is converted to glucose. Another possible factor is the moderate increase in metabolic rate that was found in a few cases in this study.

Hyperglycemia and lactacidemia are not peculiar to burn injury but have been reported following other types of trauma,^{30,31} hemorrhagic shock,³² acidosis,³³ anhydremia³⁴ and low oxygen tension.³⁵ The degree of acidosis, dehydration and oxygen lack

necessary to produce significant metabolic abnormalities, however, is such that these factors can only have been contributory factors in the cases presented here. Similarly, although hyperglycemia has been reported following the administration of morphine,³⁶⁻³⁹ the amounts of the drug required in animals are relatively many times the dosage received by our patients. However, the fact that morphine can cause such a metabolic change should be kept in mind when considering the sedation of burned patients.

The changes in carbohydrate metabolism following hemorrhage are more applicable to the present investigation, since there are certain over-all similarities between burn shock and hemorrhagic shock.

Following hemorrhage, Robertson⁴⁰ presented evidence in cats that the liver is the site of formation of the extra glucose: the sugar content of the hepatic vein blood was higher than that of the heart blood, and ligation of the hepatic vessels prior to bleeding prevented the hyperglycemia. Brooks³² working with chronic spinal cats, showed that an intact sympathetic system is necessary for the production of the hyperglycemia. Of some interest is the fact that Govier⁴¹ was able to reverse some of the effects of hemorrhage on carbohydrate metabolism in cats by the administration of large doses of thiamin chloride.

Most investigators working with burns have emphasized the role of the adrenal glands in the production of abnormalities in the carbohydrate metabolism. Hartman,⁴² working with cats, found an increase in the circulating adrenaline, as measured by the pupil-dilatation test, and a depletion of the adrenaline content of the adrenal glands. Clark and Rossiter¹² have demonstrated some differences between the action of adrenalin and the effects of burn injury. The liver glycogen was increased in animals receiving adrenalin but not in burned animals, and, secondly, liver slices from burned rabbits did not readily form glycogen from glucose in vitro, whereas liver slices from animals receiving adrenalin were able to synthesize glycogen.

Browne⁴³ and Cope et al.⁴⁴ found increased 17-ketosteroid excretion in the first few days following burns, which was followed by a decrease below normal values. Greenwald and Eliasberg⁸ working with rabbits, and Olbrycht,⁴⁵ Weiskotten^{46, 47} and Mallory,⁴⁸ studying patients, have found adrenocortical hypertrophy and a marked depletion of the lipoids. When the burn was severe there was actual necrosis of the cortical cells.

Sayers et al.⁴⁹ state that in burns the adrenal glands are stimulated to exhaustion, and the degree of response is that described in their classification as Type III.

Adrenalectomy was found by Slocum and Lightbody⁶ to prevent the lactic acidemia but not the hyperglycemia in burned rabbits. Clark and Rossiter¹²

found that adrenalectomy did not completely abolish the hyperglycemia and lactic acidemia. It therefore appears that although the adrenal glands may play an important role in the production of abnormalities in carbohydrate metabolism following burns, the entire picture cannot be explained on this basis, and, indeed, the effect of the adrenal glands may be of a secondary nature.

Pathologic changes in other organs following burns have not been consistently found. With conservative surface treatment, which precludes the use of tannic acid and other substances, which have been found to produce focal necrosis, little or no pathologic change in the liver has been observed in our autopsy material. No specific lesions have yet been reported as occurring in the pancreas. The pituitary gland itself has not been studied, so far as an examination of the literature reveals, although Christophe⁵⁰ has described a so-called "burn lesion" in the brain. He found this lesion in the region of the hypothalamus following burning or even after the transfusion of blood from burned animals into the cerebral circulation of a normal animal.

From the foregoing, it appears that there are many possible explanations of the biochemical changes mentioned in this paper. Our own evidence does not permit any statement of the primary cause at the present time. It is not improbable that, whatever the cause is, increased glycogenolysis and possibly gluconeogenesis could have accounted for the findings presented here. It will be necessary to make studies of the actual muscle and liver glycogen reserves of the patients to gain support for this view.

It is already apparent in the small series of 35 patients presented in this report that a marked hyperglycemia associated with lactic acidemia and acidosis go hand in hand with a poor prognosis. So, too, does the counterpart of these findings, namely, the presence of third-degree burns involving more than 25 per cent of the body surface.⁵¹

Although it may be argued that, in general, patients do not die from the biochemical changes reported here, nevertheless the effect of the burn trauma on the organism as a whole must indeed be profound in order to produce such changes in carbohydrate metabolism as are shown in Cases 14 and 29. In any event, from the therapeutic point of view it seems reasonable to suppose that the high blood sugar and lactic acid are obtained at the expense of the carbohydrate reserves of the body. Since in a few of the patients reported here added glucose could be metabolized in the face of a hyperglycemia, it seems reasonable to replace the depleted carbohydrate reserves by the administration of glucose, and to attempt by whatever means possible to increase, in the future, the utilization of carbohydrates by the burned patient. Such a therapeutic approach may well be of benefit.

SUMMARY

In a study of 35 consecutive burned patients, a high incidence of hyperglycemia, lactic acidemia and a moderate reduction in the carbon dioxide combining power of the plasma were found.

There is a high degree of correlation between these abnormalities of carbohydrate metabolism and the severity of the burn.

The few glucose-tolerance tests that were made indicate that in some severely burned patients with hyperglycemia there remains a considerable ability to metabolize added glucose.

There was no evidence of liver damage in these patients as a result of the burn injury. In the few cases in which liver damage was found, it was present before the injury, being for the most part an alcoholic cirrhosis.

Some of the possible physiologic and pathologic bases for the abnormalities of carbohydrate metabolism following burns have been discussed.

The abnormalities in carbohydrate metabolism that have been presented are not inconsistent with the presence of an increased glycogenolysis, together with a possible gluconeogenesis from protein.

It is suggested that additional glucose be given early to burned patients.

We are indebted to Drs. George R. Minot and Charles C. Lund for the interest shown in the development of this work, and to Professor R. A. Peters of Oxford, England, for permitting us to examine the data of Clark and Rossiter prior to publication. The technical assistance of Miss Alice Ballou, Miss Dorothy Keller, Miss Mary Maloney, Miss Jeanette Maioli, Miss Gladys Roberts and Mr. Theodore Kissel is gratefully acknowledged. Dr. George Bottomley kindly permitted us to include Case 32, which was under his clinical care. The clinical and metabolic records were the work of Miss M. Morrow and Miss A. H. MacDonald.

WAR NEUROSIS*

SURGEON (R) SAMUEL H. EPSTEIN, U.S.P.H.S.†

BALTIMORE

DURING the last world war, military psychiatry constituted a major medical problem.¹ In the course of the postwar years, aggregating nearly a generation, the enormity of the nation's psychiatric problems became obvious to the Veterans Administration, to which the care of the last war's medical problems were entrusted. Since the beginning of the present war, much emphasis has been laid on psychiatry, not only from the standpoint of therapy but also in its preventive aspects. The term "shell shock," coined in the last war, was recognized as a functional nervous disorder and soon gave way to the term "traumatic neurosis of war," a disease in which the trauma was considered to be psychologic. With realization of the heavy burdens carried by the Government with respect to the care of neurotic veterans, medical efforts at the start of the present war were directed toward the screening of psychoneurotics and the early recognition and treatment of the symptoms of war neurosis. The medical literature is replete with contributions by neuropsychiatrists; much has been written on the subject of war neuroses — descriptive, statistical, interpretive and dynamic.²⁻⁷ Most important in medicine, however, is a consideration of the etiology, pathology and therapy of this condition. It is the purpose of this paper to present some observations bearing on these problems.

First, it is necessary to define clearly what is meant by war neurosis and to clear up the terminology by which the topic is bound in the literature. The term "shell shock," already alluded to, proved to be a misnomer. Moreover, it is cogent to point out that the term "neurosis" is not fashionable in military circles because of its effect on the morale of the troops. Thus, the substitution of many different terms occurred, for example, "war fatigue," "exhaustion," "operational fatigue," "combat fatigue," "flying stress," "pilot fatigue," "war nerves," "war weariness" and "war jitters." It is obvious that one must rid oneself of this verbiage in order to have a normal "war neurosis." One must confess that with rabid also is not particularly desirable, because Mallory,⁴⁸ who has little or nothing to do with the cortical hypovivian life.

the lipoids. Over the so-called "war neurosis" actual necrosis of a psychoneurotic history and the

and assistant in neurology,

the stresses of combat service, and quite logically are more prone to do so than the non-neurotic are excluded from the group of patients with true war neuroses. The second criterion demands a combat experience of sufficient intensity to precipitate the neurosis. The immediate precipitating factors are of essential significance in this condition, in contrast to the deep-seated psychologic conflicts that are important in the true psychoneurosis unrelated to the war experience. Two other criteria must be satisfied to establish the diagnosis of war neurosis: an acute onset of irritability approximating a constant state of panic, and a relatively quick cure in the acute cases. Thus, war neurosis is a clinical entity characterized by the appearance in a previously stable person of nervous reactions precipitated by a severe catastrophic experience and amenable to quick recovery.

The characteristic symptom of this disorder is the repetitious catastrophic nightmare that has been described in observations of patients in the front lines. This consists of repeated re-enactments of the threatening combat experiences the patient has endured in cumulative fashion. As a result, sleep is disturbed and the patient is harassed by terrifying nightmares. Fear dominates the picture, even in the waking state and, with the increasing fatigue due to insomnia, produces the physical signs of tension and anxiety. The patient usually shows extreme restlessness, irregular tremors, exaggerated reflexes, excessive sweating and a frightened facies resembling the Parkinson attitude. Instead of the anxiety picture, some patients show a listless apathy reminiscent of the affectless schizophrenic.

The so-called "startle reaction" is the second characteristic of war neurosis. Sudden noises, by day or by night, produce in the patient a sudden start, accompanied by the physiologic manifestations of anxiety — tremor, dilated pupils, increased sweating, dry mouth, flushing or pallor and palpitation. No malingerer can successfully imitate this delicate timing of the physiologic effects of anxiety. Not infrequently the startle reaction breaks over into actual panic; the patient runs to the railing of the ship and attempts to jump overboard, screams hysterically or stands transfixed, laughing and crying uncontrollably.

Another sign germane to the clinical picture has been termed "a subtle personality change." The patients become morose, sullen, irritable and intolerant of their shipmates. They do not socialize in a normal way; they seek companionship in drinking; they show indecision and have inner feelings of unrest. It is not always easy to distinguish this personality change from that which accompanies a major psychoneurosis or psychosis. is

to be emphasized that this is not a cardinal sign of war neurosis, and the condition may exist without this phenomenon. There is still a fourth clinical manifestation, also not essential for the diagnosis, namely, a guilt reaction with emotional depression. This is manifest in many survivors of disasters in which a number of the original group were lost.⁸

With this description of the symptomatology of war neurosis, a few illustrative case histories will be presented.

CASE REPORTS

CASE 1. C.B., a 44-year-old, married Coast Guard lieutenant, was admitted to the United States Marine Hospital in a state of severe anxiety characterized by insomnia, terrifying nightmares, tremulous speech with inarticulation and hypersensitivity to noises. He had been in the Navy since 1917 and had served the Coast Guard continuously for the past 20 years. He was on sea duty most of the time, and worked up from the ranks, becoming a senior lieutenant a year previously. He was always in good health, with a stable personality. For the last year and a half he had been on active duty in the South Pacific as chief engineer on a transport ship, working 16 to 20 hours a day in torrid heat, subjected to continual air raids and witnessing the death of his shipmates and even of officers sent to relieve him. During the past few months he had become physically exhausted and had shown signs of dehydration. He felt himself slipping until he could no longer control his nerves. He was unable to sleep, was disturbed by nightmares and was easily startled by the noises in the engine room. While standing watch he was overcome with fear and became tense and tremulous. He was irritable, morose and practically inarticulate, and was finally returned to the United States, arriving in a state of collapse.

When examined on admission a month later, the patient showed a rugged physique, coarse, generalized tremors and an expressionless facies. Speech was inarticulate. He was extremely tense and anxious and appeared to be confused. He realized that his mind was not working well, and he felt utterly hopeless about his future. He was oriented and showed no memory defects. He was still suffering from terrifying nightmares and fear of the slightest noises. This continued during the first part of his hospitalization and was punctuated by startle reactions to the sound of the practice air-raid sirens.

After 2 weeks of intensive treatment with large doses of bromides and chloral hydrate, the patient showed considerable improvement. Psychotherapy was given in the form of reassurance regarding recovery and free discussion of his combat experiences. Sedation was continued for the next 4 weeks in decreasing dosage. After 2 weeks of freedom from symptoms without medication, he was discharged home fully recovered and reported for active duty a month later.

CASE 2. G.S., a 35-year-old merchant seaman who had been going to sea for 12 years, came to the hospital because of severe insomnia of 5 months' duration. He served in the Navy for 4 years and was honorably discharged in 1931. He was always in good health and never showed signs of nervous instability. Since the beginning of the present war he had sailed on tankers. About a year previous to admission his ship was torpedoed twice, and for the first time he became acutely aware of the dangers of the sea in wartime. During his last voyage he was on a freighter carrying a cargo of explosives and traveling without convoy or protecting planes. He began to have vomiting spells, frequency of urination, thumping of the heart and spasms of shaking and was startled by noises.

On examination the patient looked wan and drawn. He showed coarse tremors and hyperactive reflexes. He was tense and apprehensive and admitted that he had been disturbed by the constant threat of danger on the high seas. He talked incessantly about the ship's traveling alone without any protection whatsoever and carrying a dangerous cargo, exposing him to certain death in the event of a submarine attack. He suffered from nightmares of fierce torpedoing of his lone ship.

With heavy and was treated for further

continued for a week he improved
: Maritime Service Rest Center

CASE 3. M.A., a 21-year-old married merchant seaman, entered the Maritime Service Training School a year previously and had been going to sea for the last 5 months. He was the second youngest of six siblings and had an older brother who was also in the service and was injured on the same ship. He attended school up to the seventh grade and after training in a vocational school became a welder. He had had no previous illnesses.

During the last voyage, his ship was torpedoed and sunk, and he was rescued from a life raft by a destroyer and taken to North Africa. He was trembling with fear, was unable to sleep or eat and vomited continually throughout the trip. Whenever a depth charge went off, he became terrified and wanted to jump overboard. On arrival home a month later, he showed the typical symptoms of anxiety. His sleep was disturbed by terrifying nightmares, and his stomach was constantly upset.

On examination the patient showed generalized tremors, vasomotor instability and hyperactive reflexes. He found it difficult to talk, the words sticking in his mouth. He became emotionally unstable when he attempted to describe his terrifying experiences at sea. He admitted that he was more scared than sick, and he could not completely wipe out the memory of his experiences. He was put on sedation and was followed as an outpatient for a few weeks. He received tremendous solicitude from his wife and friends and finally had to be hospitalized on account of an increase in his symptoms.

With mild sedation in the hospital, followed by a period of rest in the Maritime Service Rest Center, the patient's symptoms largely subsided. He was extremely anxious to return to sea with his brother, who had recovered from his injuries.

CASE 4. R.T., a 42-year-old merchant seaman who had been going to sea for several years, and whose ship was torpedoed in January, 1942, continued on duty throughout the following year. He was on a long voyage around Russia and had been blockaded in port there for 10 months. He suffered from inadequate and insufficient food and was greatly disturbed by the tremendously high prices that he had to pay for the necessities of life.

When the patient finally returned to the United States, he became tremulous and fearful and found that he was much dissatisfied with conditions here. He became sullen and morose and took to heavy drinking. He showed extreme hypersensitivity to the slightest noises and was particularly oppressed by practice air-raid sirens. He was unable to sleep and had nightmares picturing life in Russian ports.

On frequent interviews in the hospital, it was learned that the patient had been in rugged health and was extremely fond of seagoing life. He felt acutely the importance of sailing the ships to aid the total war effort. He had numerous complaints about the strategy of the American ships overseas, and could see no reason why he was required to remain completely idle in a Russian port for long periods of time. He showed no physical abnormalities other than general tremulousness and the startle reaction to the slightest noise. He showed considerable bitterness toward the Government for what he considered incompetency in the war plans.

With strong sedation he quieted down considerably, and he was given an opportunity to air his views about the factors of morale in the Merchant Service. After a few weeks he could no longer remain in the hospital and left to return to sea.

CASE 5. G.B., a 23-year-old, married merchant seaman, was seen in the outpatient department in an anxiety state consisting of jittery feelings, sensations of tightness in the stomach, vague pains in the chest and confused thinking.

The patient attended high school and began to work in various factories at the age of 17, and later worked on fishing boats around New York. He joined the Maritime Service in January, 1943. On his first trip the ship was torpedoed and sunk, and he was rescued from a lifeboat by a destroyer, and after a few days was transferred to an American transport and brought home. He had difficulty in sleeping and experienced bad dreams about air-raid bombings and submarine attacks. For a month it was a struggle for him to decide whether or not to return to sea, but he finally decided to do so, since he did not wish to be accused of taking the easiest way out by being drafted. On his next trip in July, after being subjected to repeated bombings from the air, his symptoms increased. After the ship was torpedoed and

sunk, he was rescued and brought home as a passenger on another ship. He was terrified by seeing many of his shipmates killed and others removed to hospitals overseas. He had been home for the last 6 weeks, and had become increasingly worse. His wife noticed that he was extremely irritable and morose, and that he complained of numerous symptoms referable to his stomach. He was startled by the slightest noise and was unable to sleep on account of terrifying nightmares.

On examination the patient showed no physical abnormalities except for general tremulousness. He was mentally clear and talked rationally. He showed some anxiety about the risks of sea duty in wartime, but he felt ready to go back to sea on account of the vital importance of sailing the merchant ships in the war effort.

He was persuaded to go to the Maritime Service Rest Center, where he remained for a short time. He was then advised to take a shore job for a few weeks, and gradually improved, regaining his ability to sleep and losing his stomach symptoms.

As already mentioned, the immediate precipitating factors are of primary etiologic importance in war neurosis.⁹ Nevertheless, a number of environmental factors, physical and mental, must be given consideration in the etiology. These include physical exertion, loss of sleep, insufficiency and irregularity of meals, continued exposure to bodily danger, loss of comrades in death, repeated near escapes from the enemy, frustration of necessary retreat and poor morale. It is not possible to evaluate the number and the severity of the factors necessary to produce a nervous breakdown in any given person, since there is great variability in the response of normal men to stresses. Those encountered in the type of case discussed here are peculiar to war conditions and are characteristically cumulative. It is significant that most of the patients do not break down after the first traumatizing experience, but usually after repeated exposure. This was true of the British experience in the evacuation of Dunkirk, when large numbers of men developed acute war neuroses.¹⁰

It is obvious that physical fatigue plays a large role in reducing the normal mechanisms of defense against emotional disturbance. Fatigue is important not only in land troops but also in men of the naval forces whose rest is usually broken by general alarms, drills, abortive attacks and the like. Fatigue has been such a prominent factor in the etiologic background of these cases that it has been suggested as an alternative term for the syndrome of war neurosis. Physical exhaustion, complicated by varying degrees of starvation, avitaminosis, dehydration and acidosis, is frequently met with.

Of more direct importance in the production of symptoms is the setting of interpersonal relations. In the war situation morale is a potent force in maintaining stability.¹¹ It is often found that the patient entered the combat situation without confidence in his leader. Any incident that strengthens faith in the leader lessens the occurrence of neurotic symptoms. Careful and adequate training is also of great importance in the prevention of war neurosis. It has been repeatedly observed that in the heat of battle men react at an automatic level and

that fear reactions are much less frequent in those performing duties that they know well. Another factor often encountered is the intolerable sense of personal danger felt by a man surrounded by new shipmates whose conduct under fire he has not had time to estimate. He is consequently beset with feelings of doubt and insecurity, adding to the fear reaction.

Other psychologic factors, already referred to, likewise operate through the medium of fear. Prolonged exposure to bodily danger without relief has a tremendous effect on even the hardest of personalities. Repeated near escapes from the enemy and the constant necessity of retreat produce a profound feeling of frustration. The subject is hence unable to discharge his aggression toward the enemy and, witnessing the death of his comrades about him, he becomes paralyzed with fear. These accumulated fear reactions give rise to anxiety and form the essential etiologic basis on which the immediate combat experience operates to precipitate the symptom complex called "war neurosis."

It is now in order to suggest the pathology of this condition by explaining the mechanisms of fear and anxiety in the organism. From the work of Cannon and his colleagues,¹² it is clear that the majority of the symptoms of fear and anxiety are related to the function of the sympathetic-adrenal apparatus. When such a state of sympathetic excitement is long continued, secondary effects result from the glycogenolysis, insomnia, anorexia and hyperventilation that accompany the prolonged adrenal activity. The emotion of fear is a perception in consciousness of these intense and complex somatic changes. In the light of Pavlov's conceptions, this emotion can be considered as a neurochemical reflex that is conditioned by environmental factors to reaction or inhibition by means of various summations, extinctions and facilitations. The fear reaction is a complex reflex, with its efferent arc proceeding through the sympathetic-adrenal innervation from the autonomic centers of the hypothalamus; these in turn are controlled from the cerebral hemispheres, whose function, in the words of Pavlov, is "that of reacting to signals presented by innumerable stimuli of interchangeable signification." Anxiety is an overaction of this fear reflex. By repetition and summation of the stimulus of danger, with constant reinforcement and lack of time for extinction, the reflex becomes either highly facilitated or conditioned to wider and wider associations, until the whole environment becomes an appropriate stimulus of fear. Moreover, analogous to the so-called "analyzer breakdown" of Pavlov's dogs, if the powers of adaptability to danger are overtaxed they may be entirely lost, the fear reaction being left disorganized and uncontrolled. Finally, interference with this mechanism by organic factors of fatigue or disease plays

a part in the cortical breakdown. It may be said, then, that in war neurosis occurring in the setting of continued combat without relief, a dissociation occurs between the cortical activity and the subcortical emotional and vegetative functions.

There are described in the literature other clinical pictures under the heading of war neuroses. They include severe exhaustion states; confusional states varying from mild disorientation to profound delirious reactions with hallucinations; dissociated states, such as amnesias, fugues and localized hysterical phenomena with various visceral disturbances; and acute psychotic and psychopathic disorders resembling the depressions, manic excitements and schizoid reactions. These represent a wide variety of neuropsychiatric conditions and are to be distinguished from the uncomplicated war neurosis. Those cases in which the patients develop complicating symptoms of all gradations of psychoneurosis, psychosis and organic brain disease should be grouped with the classic neuropsychiatric conditions common to civilian practice in which the combat situation is only an incident. In the cases presenting secondary signs, the treatment, prognosis and disposition are exactly the same as those for the same disability occurring in peacetime, except as they may be affected by the secondary gain possible under the pension system to any disability occurring during war. Unfortunately, this has proved to be an extremely serious obstacle in the handling of veterans of World War I.¹³

From the foregoing discussion, it may be seen that war neurosis is a clinical entity with specific diagnostic criteria and etiologic factors, having its pathologic basis in fear. The therapy of the condition is likewise specific. Foremost in importance is the principle of early treatment in the forward areas. The further away from the combat zone the patient is and the longer the treatment is delayed, the poorer is the prognosis. The latest Army figures show that 80 per cent of the patients treated without delay were returned to duty, whereas only 5 to 10 per cent of those evacuated to the rear were cured.

The active therapy is relatively simple and includes two primary considerations: rest and emotional desensitization of the patient to the traumatic combat experience. Rest is obtained by the use of barbiturates to produce profound and prolonged sleep. Supportive treatment with fluids and nourishment should be employed as indicated. Emotional desensitization may be accomplished by simple psychotherapy consisting of reassurance, exhortation, support and encouraging verbalization of the patient's fears. Hypnosis may be used, but deep analysis should be avoided. It is the precipitating factor of the combat situation that is basically significant in war neurosis, and not the unconscious conflicts such as exist in the true psychoneurotic. Group therapy has a place in

dealing with large numbers of these casualties. Another technic of desensitization now in general use consists of allowing the patient to re-enact the frightening memories of his combat experience during narcosis produced by the intravenous administration of amytal sodium. This enables the patient to discharge the content of his fears and recover his amnesias, and to obtain reinforcement through suggestion and reassurance on the part of the physician.

Return to duty should be accomplished as soon as possible, but it is important that the patient be given a certain period of time to "digest" the emotional turmoil before being exposed to another. For this purpose he should have access to a center where directed recreation and physical work are available and simple psychotherapeutic methods are in use. He should be sleeping well, having no nightmares and exhibiting no startle reaction before he is allowed to leave. Those cases requiring further treatment are no longer useful to the service and come under the care of the Veterans Administration, when a well-rounded program of active psychiatric treatment and elimination of the complications incident to continuing disability benefits must be established. This is of vital importance in order to avoid repetition of the governmental burdens of the last war with respect to the care of veterans with neuropsychiatric disabilities.

SUMMARY

War neurosis is a clinical entity characterized by the appearance, in a previously stable person, of fairly constant nervous reactions precipitated by a severe catastrophic experience and usually amenable to quick recovery. The essential etiologic basis lies in accumulated fear reactions amounting to a state of anxiety under continued combat conditions without relief. The mechanism consists of overaction of the sympathetic-adrenal apparatus and the conditioned-reflex reactions of fear, as a result of which a dissociation occurs between cortical activity and subcortical emotional and vegetative functions.

CLINICAL NOTE

SPONTANEOUS PNEUMOPERITONEUM FROM AN UNKNOWN CAUSE*

REPORT OF A CASE

NATHAN SIDEL, M.D.,† AND
ABRAHAM WOLBARSH, M.D.‡

BOSTON

PNEUMOPERITONEUM may be a spontaneous, diagnostic or therapeutic condition. When it is encountered, except in the form induced for diag-

cording to Hinkel§, the case he reported was the third such report in a review of the literature, and none has been reported since.

CASE REPORT

I. N., a 63-year-old Swede, was admitted to the First Medical Service of the Boston City Hospital on May 1, 1940. There was a 2 weeks' history of an upper respiratory infection followed, 2 days before admission, by a frank chill and pain in the left side of the chest, aggravated by coughing and breathing. The past history and family history were not remarkable.

Physical examination revealed a well-developed and well-nourished male, moderately ill and breathing somewhat laboriously. Except for a reducible right inguinal hernia the positive physical findings were limited to the chest. There was limited expansion of the left chest, with increased

FIGURE 1. Roentgenogram Taken on June 3.

nosis, there is usually some lesion in the gastrointestinal canal as the causative factor. The perforation of a viscus is the usual cause, and in some cases the perforation is a slowly developing leak rather than a sudden puncture.

This case report deals with a rarely reported finding, spontaneous pneumoperitoneum without demonstrable cause and without symptoms. Ac-

tactile fremitus, dullness, an increased whispered voice and a few medium moist rales at the left base. The temperature was 100°F., the pulse 96, and the respirations 26. A diagnosis of pneumonia of the left lower lobe was made and the patient was started on routine pneumonia care and sulpyridine. Both the sputum and the admission blood cultures were reported as positive for Type 8 pneumococcus. Subsequent blood cultures were negative. X-ray examination of the chest the day after admission also indicated pneumonia of the left lower lobe. The patient became afebrile on the 2nd day and remained so the entire 1st week, except for a rise in temperature to 100°F. on the 2nd day. The sulpyridine was discontinued on the 3rd day.

On the 5th day, slight abdominal distention was noted and a few medium moist rales were heard at the base of the

lung fields. The distention became progressive and firm. The patient had no complaints except for general discomfort due to the distention. He was given enemas, flaxseed poultices and pituitary extract and rectal tubes were passed, with little reduction in the distention which continued unabated for slightly more than 3 weeks, when it began to decrease progressively. In the 3rd week, because of a continued daily slight rise in temperature and persistence of rales at both bases, another course of sulfapyridine was started and continued for 5 days. The patient again became afebrile for over a week. This was followed by a few days of elevated temperature. From the middle of the 5th week until discharge in the 6th week, he remained afebrile and asymptomatic.

X-ray examination of the chest on the 17th day showed diffuse clouding at the lower half of the left lung field and also a concave shadow at the right base, which was interpreted as being suggestive of a large amount of free air beneath the diaphragm. A flat plate of the abdomen taken on June 3

ination on August 10 (Fig. 2) showed complete disappearance of the pneumoperitoneum.

A review of the past history failed to reveal any abnormal gastrointestinal background. There were at no time complaints referable to the gastrointestinal tract, either during the hospital stay or subsequent to discharge.

Laboratory studies during the hospital stay were not remarkable except for one urine specimen containing sulfapyridine crystals. The stools were negative for occult blood on several occasions. The hemoglobin ranged between 78 and 84 per cent (Sahli) and the white-cell count varied between 7500 and 12,000. The blood smear differentials were normal. A blood Hinton test was negative. The blood non-protein nitrogen on two occasions was 40 and 59 mg. per 100 cc.

It is generally recognized that the demonstration of pneumoperitoneum, except for the form

FIGURE 2. Roentgenogram Taken on August 10.

showed an extensive pneumoperitoneum with the liver and spleen outlined (Fig. 1). The abdominal organs shifted with a change in position. Fluoroscopy showed normal movements of both sides of the diaphragm. A barium meal passed normally through the esophagus and entered the stomach without delay. There was no evidence of gastric or duodenal ulcer.

After complete recovery from the pneumonic process and reduction in distention, a gastrointestinal series was performed, which was interpreted as showing hypertrophic gastritis. Lipiodol was injected into the lungs to discover whether a fistula into the peritoneum had occurred through the diaphragm. The results were entirely within normal limits except for slightly thickened pleura on the left. A barium enema was negative. At that time (July 5) the x-ray examination still showed air under the diaphragm.

On July 27 a fluoroscopy of the abdomen demonstrated complete absence of air in the peritoneum. X-ray exam-

induced for diagnostic purposes, is indicative of a perforated viscus due to a peptic, typhoidal, tuberculous or carcinomatous ulcer in the stomach or intestine or to serious abdominal trauma.

Occasionally, pneumoperitoneum is not demonstrable even though a definite perforation in the gastrointestinal tract has taken place as shown at operation or autopsy. When pneumoperitoneum is present, however, one can generally assume that perforation has taken place. Cases are reported of recovery from perforation without surgical intervention and the subsequent disappearance of the pneumoperitoneum, but in these cases a gastro-

intestinal lesion is diagnosed either by x-ray evidence or from the history. In this case, no history or x-ray findings of a gastrointestinal abnormality were obtained, and the patient remained essentially free of abdominal symptoms.

SUMMARY

A case of pneumoperitoneum discovered accidentally during the course of pneumonia without any symptoms referable to the pneumoperitoneum is reported. There was a subsequent spontaneous

disappearance of the pneumoperitoneum. This case is considered unusual because no gastrointestinal abnormality was shown by the history, laboratory tests or x-ray investigation. There was x-ray evidence of the marked pneumoperitoneum and the complete disappearance of such findings after a three-month interval.

The possible relation of a pneumoperitoneum to the pneumonic process by the formation of a fistula was investigated, but no basis for it was discovered.

MEDICAL PROGRESS

MODERN CONCEPTS OF RENAL STRUCTURE AND FUNCTION IN CHRONIC BRIGHT'S DISEASE (Concluded)*

STANLEY E. BRADLEY, M.D.†

BOSTON

FUNCTION

During the past year Smith^{42, 43} has published an engaging and intimate account of the development of the modern concepts and methods of renal physiology. As he points out, the modern era began with the appearance of Cushny's⁴⁴ monograph, *The Secretion of Urine*, and the promulgation of his "modern view." Cushny succeeded in establishing order and coherence among the mass of data that had accumulated by rejecting all of the many existing theories and postulating but two renal excretory activities—glomerular filtration and differential tubular reabsorption. The introduction of the microcapillary pipette by Richards⁴⁵ to obtain samples of glomerular filtrate and tubular urine directly for analysis firmly established the doctrine that the glomerular filtrate is a simple ultrafiltrate of the plasma. Although the early work was done on cold-blooded animals, recent work has extended the direct proof of the validity of this hypothesis to mammals.^{46, 47} For many years the influence of Cushny's ideas and the absence of solid evidence excluded the possibility of tubular excretion, but in 1923, Marshall and Vickers⁴⁸ showed that phenol red was excreted by the kidney even when the perfusing pressure was too low to permit filtration. Moreover, they noted that more phenol red appeared in the urine of the normal animal than could possibly be excreted by filtration alone since most of the dye is bound to the plasma protein leaving only a small fraction available for filtration. Therefore, it seemed reasonable to conclude that a process of

active tubular excretion must be concerned in the renal elimination of phenol red. To this evidence were added supportive data derived from a study of aglomerular fish.³⁵ In these animals urine is secreted in the absence of a filter bed and all the constituents that may be found in urine, save protein, glucose and ferricyanide, are voided. It soon became evident that quantitative study of tubular excretion and reabsorption could be possible only if a means of measuring the rate of glomerular filtration could be devised. Filtration rate could then be used as a standard of reference, since the excretion of any substance in excess of the amount filtrable would indicate a contribution by the tubules, and conversely any deficit would indicate net reabsorption.

Clearances

Quantitative studies of renal function began with studies of urea excretion and led to the development of the clearance concept. When Van Slyke first introduced the term "clearance" he had reference to the virtual volume of blood completely cleared of urea in each minute by the kidney, but as Smith⁴² points out, the term has acquired broader meaning in recent years and "taking conceptual wings, has become a generalized notion applicable to all aspects of renal excretion." The first concept of the urea clearance was confused by the introduction of a square-root radicle into the term at low urine flows, "a mathematician's device to squeeze a correlation out of data in which a simple correlation is not present."⁴² Once it was appreciated that the use of the square-root radicle had no physiologic justification, the situation was simplified: the clearance term could be applied to any substance, and the ratio between the quantity of the material

*From the Evans Memorial, Massachusetts Memorial Hospitals, and the Department of Medicine, Boston University School of Medicine.

†Instructor, Department of Medicine, Boston University School of Medicine; assistant physician, Evans Memorial, Massachusetts Memorial Hospitals.

excreted each minute and its concentration in plasma or blood could be expressed in terms of a volume of plasma or blood cleared of it per minute. If a substance is to be used in measuring filtration rate it must be excreted only by filtration. The quantity cleared is the amount contained in the plasma that passes through the filter; its plasma clearance is equal to the filtration rate. In a phlorizinized animal, glucose is no longer reabsorbed and since there is no tubular excretion of this substance, it follows that, in this situation, the glucose clearance must be equal to the filtration rate. It has been found that glucose clearance in the phlorizinized animal is equal to the clearance of inulin, mannitol, sorbitol or dulcitol when these determinations are made simultaneously.⁴² In the normal animal and in man, the clearance of glucose is zero, whereas the values for the other substances are identical with those in the phlorizinized animal. Hence there is good evidence that these substances can be used to measure filtration rate.

If all the blood passing through the kidney is completely cleared of a given substance, then the measurement of this clearance is equivalent to the measurement of blood flow. Among substances found to be approximately so cleared are Diodrast and sodium para-amino hippurate. Of course, one would not expect absolutely all the blood flowing through the kidney to be cleared, since a portion of it perfuses nonexcretory tissue. Nevertheless, recent determinations of the renal extraction ratio of sodium para-amino hippurate reveal that 90 per cent of the material, on the average, is removed on one circulation through the kidney.^{41, 49} Therefore it seems fair to assume that the clearance of this material (and of Diodrast) is a measurement of the blood perfusing functional excretory tissue, that is, of effective renal blood flow.

With such methods for measuring glomerular filtration rate and renal blood flow, students of renal physiology and disease have been able to move on to quantitative studies of renal hemodynamics and tubular activity. For example, the ratio between filtration rate (GF) and blood flow (PF), namely, the filtrate fraction (GF/PF), is the percentage of the renal blood flow filtered at the glomerulus. This value is a function of a number of variables, including intraglomerular pressure, plasma oncotic pressure, intrarenal pressure and the viscosity of the blood. Smith and his associates⁵⁰ have undertaken an analysis of these variables with the aim of ascertaining the relative effect of vasomotor activity in the afferent and efferent glomerular arterioles. They showed that similar changes in all values result from afferent arteriolar control of blood flow, that is, a fall in GF, PF and filtrate fraction during increased afferent resistance, and a rise in all with decreased afferent resistance, whereas a constant filtration rate is maintained over a wide range of renal blood flows by efferent arteriolar

control of intraglomerular pressure. Since the filtration rate tends to remain constant in normal animals and man, and also in hypertensive patients with a wide range of decreased renal blood flows, they concluded that the prime determinant of glomerular dynamics is efferent vasomotor activity. Lampport,^{51, 52} however, in a subsequent analysis of the same data took issue with this conclusion. On the basis of formulations of afferent and efferent arteriolar resistances derived from Poiseuille's law, he deduced that both sets of arterioles must be active to maintain a constant filtration rate since, contrary to Smith's hypothesis, his calculations showed that efferent control would be expected to change filtration rate from zero at low blood flows to a maximum at normal flows and back to zero at high rates of renal blood flow, an obviously impossible physiologic situation. Shannon,⁵³ on the other hand, criticizes both hypotheses for their dependence on assumed constant values for immeasurable variables and points out that Lampport's treatment does not recognize the importance of the elastic resistance of the glomerular capillaries. Lampport⁵⁴ admits the justification of the first criticism, but claims that his calculations are flexible enough to account for all conceivable factors. The fundamental difference between these two hypotheses can best be seen when they are applied to an interpretation of the hemodynamic events of essential hypertension. Early in the course of this disease, the filtrate fraction increases as a result of the diminished blood flow through the kidney without significant change in the filtration rate. Smith⁵⁰ places the site of the vasoconstriction responsible for the decreased blood flow in the efferent arteriole, whereas Lampport⁵⁵ believes that the resistance in both arterioles is increased with afferent outweighing efferent vasoconstriction. Undoubtedly further analysis will resolve the differences between these two points of view.

The application of the clearance methods to the measurement of the dynamic activities of diseased kidneys has been severely criticized because of the over-all character of clearance measurements.⁵⁶ Thus the demonstration of hypertrophy and atrophy in the same kidney implies a compensation on the part of some units for the decreased function in others, allowing the average function of the two categories measured by clearances, to remain unchanged in spite of the marked local alterations that have occurred. This type of behavior has been demonstrated functionally, as well as anatomically, in dogs with chronic interstitial nephritis. These animals have been shown to handle a dye, trypan blue, in a manner different qualitatively and quantitatively from the normal since it appears that filtration with or without reabsorption and actual diffusion into the tubular lumen may take place. It is asked, then, Why may there not be a similar change in the manner in which inulin is excreted,

making it unsuitable as a measure of the filtration rate? Furthermore it has been shown that renal tubules severely damaged by uranium cease to excrete Diodrast and they allow inulin to diffuse back into the blood.⁵⁷ These criticisms appear to have been answered satisfactorily.⁵⁸ It is admitted that the clearances are average figures but, that, considered in relation to the total mass of active tubular tissue, they continue to have significance in assessing the relative changes in filtration rate and renal blood flow. Furthermore it has been demonstrated that the clearances of inulin and mannitol in glomerulonephritis,⁵⁹ eclampsia⁶⁰ and the profound renal hemodynamic changes of shock⁶¹ are in agreement. If molecular diffusion in either direction between the tubular lumen and the blood occurred, then agreement of these values could not be expected, since the rates of diffusion would not be equal for such dissimilar molecules. It is immaterial for the measurement of blood flow how Diodrast or para-amino hippurate is excreted, provided the blood is entirely cleared. In renal disease, blood perfuses a smaller and smaller mass of excretory, relative to nonexcretory, tissue and as a result, the over-all extraction ratio would be expected to decrease. Obviously, with extreme damage the Diodrast (or hippurate) clearance fails to measure even approximately the actual renal blood flow. As a matter of fact, extraction ratios as low as 55 per cent have been observed in a case of chronic diffuse glomerulonephritis in the nephrotic stage when over-all renal function was not greatly impaired.⁴⁹ This does not mean, however, that in such cases these clearance methods should be discarded as valueless. They continue to measure the blood flowing to residual functional excretory tissue, since it is unlikely that at the low plasma levels of Diodrast (or hippurate) employed the capacity of any perfused functioning tissue is exceeded. This surmise is strengthened by the demonstration that the proportionality between the amount removed by and the amount offered to the kidney at progressively higher plasma levels remains unchanged and normal in pattern until very late in the course of glomerulonephritis.⁵⁹ This indicates that the functional tissue is handling the substance in a normal fashion and that the Diodrast (or hippurate) clearance, in these circumstances, is a valid measure of blood flow to such functional tissue.

Tubular Function

The necessity of relating the renal blood flow to the mass of functional tissue became obvious when the problems of ischemia and hyperemia, of hyperfiltration and hypofiltration in residual glomeruli and of hyperfunction and hypofunction in variously damaged tubules were considered. To understand the methods used for assaying the mass of renal functional tissue one must return to the question of

tubular reabsorption and excretion. Given a method for determining glomerular filtration, the role played by the tubules in the renal secretion of a given substance can be accurately quantitated, for example, at high plasma levels of glucose the amount of tubular reabsorption of glucose is equal to the amount filtered less the amount that appears in the bladder urine. Early in the study of tubular function it became apparent that many substances, particularly nonelectrolytes, were handled by tubular transfer mechanisms of definitely limited capabilities. For example, glucose is entirely reabsorbed from the glomerular filtrate until the load exceeds the capacity for reabsorption, when reabsorption continues at a fixed maximal rate while the excess is spilled in the urine. Similarly the excretion of Diodrast is limited by the maximal capacity of the tubules to handle it. Such maximal rates of either reabsorption or excretion are functions of the quantity of active tubular tissue. After unilateral nephrectomy the maximal rates are approximately halved,⁶⁴ and with the succeeding hypertrophy of the remaining kidney they slowly increase. Moreover, it has been shown that a clear-cut correlation obtains between glomerular filtration rate and maximal tubular activity (Tm) and that a similar relation holds for blood flow and Tm.⁶² The wide variability of the discrete functions in persons of varying size vanishes when the clearance values are expressed in terms of these factors. Hence, in disease where all functions may be depressed, a knowledge of the *effective* renal blood flow of itself may be of no value in estimating the presence of renal ischemia or hyperemia, but when related to the mass of residual functioning tissue, it may give helpful information regarding these matters.

Saturation methods, such as those used in the determination of transfer maxima, have been applied to an analysis of the distribution of glomerular and renal vascular dysfunction^{43, 63} and have, under certain circumstances, indicated the presence of co-existent hyperfunction and hypofunction. Shannon and his associates⁶⁴ have shown in the normal dog that glycosuria occurs abruptly and that all the nephrons apparently are simultaneously saturated (glucose Tm is reached) at a given level of plasma glucose. This requires a nice adjustment between the individual glomerular filtration rates and the capacity of the attached tubules to reabsorb glucose and implies an anatomic and physiologic correlation between the size of the glomerulus and its attached tubule such that the large glomeruli are attached to large tubules and small glomeruli to small tubules. If this adjustment did not obtain, glucose would begin to appear in the urine at plasma levels of glucose lower than those required to saturate all the nephrons, because at such low levels the maximal rate of reabsorption would be reached in tubules getting a larger proportional quantity of filtrate. Almost the same situation has been

found in man for both glucose and Diodrast.⁶³ With respect to the latter, the phenomenon indicates a proportional distribution of blood flow to every tubular excretory cell. Owing to this fact, a progressive elevation of the plasma level (so-called "titration" of the kidney) of either Diodrast or glucose is associated with an equal increase in the amount transferred by the tubular cells until Tm levels are reached, when the transfer rate abruptly becomes constant. This proportionality between the load and the transfer rate may be disturbed by disease. Hyperemia of some of the nephrons results in relatively higher perfusion and filtration rates allowing saturation of these units at low loads; whereas ischemia has a reverse effect. Mathematical and statistical analyses of the defects in proportionality have been published in the past year, and distribution curves for relative glomerular activity and tubular perfusion have been derived for normal kidneys.⁶³ These methods have also found application in the study of the kidney of essential hypertension.

Before turning to the application of these methods to the study of renal physiology in chronic Bright's disease, certain aspects of recent studies of tubular function must be considered with special reference to their bearing on renal disease. The discovery of maximal transfer capacity permits examination of the intracellular mechanisms by which these tubular activities are carried out. Thus, the effect of the presence of other substances that may interfere with enzymatic activity or that may enter into the reactions by which transfer is accomplished can be studied and inferences may be drawn concerning the nature of various intracellular metabolic processes. This is an extremely important consideration, since renal hypertension and other effects of renal dysfunction may arise from a derangement of intracellular activities of the tubular cells.⁶³ Shannon,⁶⁵ in an important review of this subject, has shown that the available data are consistent with an explanation of the phenomena of limited transfer in terms of the mass-action law, assuming the intermediacy of a transfer substance. During the past year, Pitts^{66, 67} has reported the results of a study of the reabsorption of various amino acids and suggests certain modifications of Shannon's hypothesis, which are necessary to explain the kinetics of amino acid transfer. It is interesting that several substances appear to compete for excretion or reabsorption by the same mechanism. Several different series of such substances have been studied. Glucose, xylose, galactose and sucrose are apparently reabsorbed through the agency of one transport system,^{63, 68} whereas phenol red, Diodrast, Hippuran,⁶⁹ Iopax, Neoipax, Skiiodan,⁷⁰ para-aminohippuric acid⁷¹ and penicillin^{72, 73} are excreted by another mechanism. In the case of the first system, preferential treatment is given to glucose, which, when present in sufficiently large

amounts, excludes other members of the group from transfer. In the second series, Diodrast appears to be preferentially excreted and glycine heads a series of amino acids, including alanine, glutamic acid and arginine,⁶⁷ that are reabsorbed preferentially in the order named. The action of phlorizin has been interpreted by some workers as an effect of competition with glucose for an intracellular transport system,⁵³ although there is evidence that it produces its effect by interference with the action of kidney phosphorylase.⁷⁴

Many tubular activities, such as water reabsorption and sodium or potassium transport, are known to be under endocrine control. It has recently been demonstrated that the hypophysis, adrenal cortex, gonads and thyroid gland are capable of affecting tubular transport systems. Hypophysectomy is followed by a decrease in Diodrast Tm and by a failure of hypertrophy to occur in the remaining kidney after unilateral nephrectomy.^{75, 76} The administration of thyroid causes increased Diodrast transfer in animals.⁷⁷ Estradiol depresses the absorption of ascorbic acid⁷⁸ and causes renal hypertrophy, possibly on the basis of interstitial edema.⁷⁹ Testosterone administration is followed by hypertrophy of both kidneys in experimental animals⁷⁹⁻⁸² and an augmentation of Diodrast Tm.⁸³ For this reason it has been suggested that the trophic effect of testosterone might prove of value in stimulating hypertrophy of residual renal tissue in the course of Bright's disease.^{81, 84} Furthermore, it was thought, that the retention of nitrogen due to increased protein building supposedly induced by testosterone administration, might serve a useful purpose in patients with nephrosis losing large amounts of protein.⁸⁵ Two cases of renal disease have been reported in which therapy was based on this rationale.^{82, 85} There is no evidence of benefit. In Cushing's syndrome due to adrenocortical tumor, no change in Diodrast Tm or Diodrast or inulin clearance was noted by Barnett and his co-workers.⁸⁶ Moreover, Heinbecker and his group⁷⁷ failed to find any renal change following the administration of cortical extract to dogs, and desoxycorticosterone, in the hands of Winkler and his colleagues,⁸⁷ failed to produce any noticeable effect during anuria. The experiments of Selye and his co-workers,⁸⁸⁻⁹³ however, revealed a profound change in the kidneys of experimental animals following the administration of desoxycorticosterone. These investigators discovered that this substance produced renal lesions in the chick resembling in every way nephrosclerosis,⁹² but it was also found that excess salt ingestion produced similar lesions.⁹³ An extension of the study to mammals (dog, rat and monkey) disclosed that desoxycorticosterone overdosage combined with the ingestion of large amounts of sodium chloride produced renal lesions similar to those of malignant nephrosclerosis in man.^{88, 89} Accompanying the development of the renal lesions

the blood pressure rose to hypertensive levels and death occurred on the basis of renal insufficiency and cardiac failure. Vascular lesions were found not only in the kidney but also in the pancreas and in the adrenal capsule. Recently it has been found that the action of desoxycorticosterone in the experimental animal may be completely blocked by methyl-testosterone.⁹⁴ What bearing these discoveries may have on the question of the etiology and therapy of human malignant nephrosclerosis remains to be seen.

Despite the sensitivity of tubular activities to many extrarenal influences, values of Tm in normal animals and man are strikingly constant and reproducible.⁶³ The maximal tubular transport rates of glucose and Diodrast have been shown to be constant and independent under a variety of experimental conditions. The administration of adrenalin and caffeine and the induction of renal hyperemia during pyrogenic reactions do not affect the values of glucose and Diodrast Tm to any significant degree.

The constancy of glucose Tm has important theoretical consequences. It has long been known that only a portion of the glomeruli are active at any one time in the amphibian kidney, and it has been supposed, on the basis of injection studies,⁹⁵ that a similar inactivity of an appreciable number of glomeruli may occur in the mammalian kidney. It has been assumed that caffeine diuresis in man follows induced activity of previously inactive glomeruli, which direct observation has shown to be the case in the frog. If this were true, a marked increase in filtration rate and in glucose Tm would be expected after the administration of caffeine because the opening up of nonfunctioning glomeruli would bring into operation nephrons previously not filtering and reabsorbing glucose, thus causing an increase in maximal reabsorptive capacity. This does not happen. On the other hand, adrenalin might be expected to shut down a number of glomeruli and to reduce Tm. Forster⁹⁶ has shown that this is the case in the frog, where glomerular intermittency can be directly observed, but no change in Tm occurs in man.⁶³ Hence, the facts "controversy the idea, carried into mammalian physiology from observations on cold-blooded animals, that any significant number of glomeruli are inactive at any moment."⁶³ In addition, direct observation of mammalian glomeruli has failed to reveal any evidence of glomerular intermittency.⁴⁷ Explanations of drug action in man based on this hypothesis must be discarded. Obviously the concept of a glomerular reserve is unfounded and the filtration rate may be taken as a measure of the filter bed.

Functional Patterns of Disease

Renal function in 22 patients in various stages of glomerulonephritis has been studied by the methods

outlined above at the Welfare Island Hospital in New York City by Earle, Taggart and Shannon.⁴¹ The earliest manifestation of the disease was an interference with the glomerular filtration rate, as one would expect on the basis of what is known of the pathology. In addition to the fall in filtration rate, renal blood flow increased or it remained at a normal level. As a result, the filtration fraction decreased from a normal level of 19 per cent to as low as 8 per cent. It is known that afferent vasoconstriction may lower intraglomerular pressure, with a fall in filtration rate and filtrate fraction. This appears to be the case in shock^{61, 97} and in chronic anemia,⁹⁸ both of which are accompanied by a decreased renal blood flow. Since in glomerulonephritis, however, the blood flow may actually increase, it appears likely that the decreased filtration rate and filtration fraction found in glomerulonephritis are attributable to impairment of filtration caused by the action of the disease on the glomerular membrane.

At first there seemed to be relatively little interference with tubular function, and it was pointed out that the resultant loss of the normal adjustment between glomerular filtration rate and the functional capacity of the attached tubule may have serious consequences, since "glomerular damage out of proportion to the impairment of tubular function should predispose to the retention of electrolyte and, incidentally, water, as is so common."⁵⁹ With progression there was a destruction of tubular tissue roughly parallel to the reduction in filtration rate, as evidenced by the fall in the Diodrast Tm. Here too, however, there was relatively greater reduction in filtration rate than in tubular mass so that the glomerular filtrate-Diodrast Tm ratio (GF/Tm) remained depressed and glomerulotubular imbalance continued to be prominent. At first blood flow was well maintained, but when the Tm was reduced to half normal, the blood flow was consistently reduced to extremely low levels. It should be noted that high blood flow-Diodrast Tm ratios (PF/Tm), denoting relative hyperemia, were not uncommon in any phase of the disease.

The low filtrate fraction remained prominent during the entire course until the appearance of hypertension or the extreme reduction of Tm in the terminal stage either considerably altered glomerular dynamics or so invalidated the measurement of blood flow that the filtrate fraction rose to normal or high levels. At that time too, there was often a reversal in the glomerular filtrate-Diodrast Tm ratio (GF/Tm). Hypertension was not necessarily related to the extent of tubular damage, although it seemed to be consistently present when Tm had been reduced to one quarter normal. During the acute stage and in acute exacerbations of the chronic disease a reduction was observed in filtration rate, Diodrast Tm, and GF/Tm, followed by a return toward the normal levels during recovery, but no

correlation was apparent between the gravity of these changes and the ultimate course of the disease. Occasionally the values returned to normal while proteinuria was still obvious. Two findings stand out in this study, namely, the predominance of glomerular impairment and the appearance of relative renal hyperemia throughout the course of the disease. These features are consistent with the pathology and with the belief that glomerulonephritis is pre-eminently an inflammatory disease.

The functional pattern of glomerulonephritis stands in striking contrast to that found in the course of nephrosclerosis. Sixty subjects with essential hypertension were examined by Goldring, Chasis, Ranges and Smith.⁹⁹ Early in the disease changes in filtration rate and renal blood flow appeared to be based upon hemodynamic rather than upon organic changes. The filtration fraction was increased as a result of decreased blood flow in the presence of an unchanged filtration rate. The authors are of the opinion that this pattern is caused by efferent arteriolar vasoconstriction that is functionally reversible (hyperemia followed the administration of pyrogenic inulin with a fall in the filtration fraction) and that it is not dependent on neural pathways (the pattern remained unchanged after extensive sympathectomy) and is therefore probably attributable to the activity of some unknown humoral agent. With progression of the disease there was a steady loss of tubular tissue manifest in the gradual reduction in Diodrast Tm, a loss that at times outran the impairment of filtration, thus indicating the presence of impotent tubules or possibly increased pressure in the glomerulus as a result of increased systemic arterial pressure. Whereas the glomerular filtrate-Diodrast Tm ratio (GF/Tm) tended to increase, unlike the situation in glomerulonephritis, the renal blood flow-tubular excretory mass ratio (PF/Tm) ranged from low normal to very low values, thus indicating relative renal ischemia. A study of the distribution of blood to its tissue substrate during hypertensive disease, however, revealed fairly uniform spread even when the disease was so far advanced as to distort markedly the anatomy and the delivery of filtrate.⁶³ Focal renal ischemia appeared to be the exception rather than the rule in this disease. The slight increase in Diodrast Tm that often followed the administration of pyrogen might have been evidence that in some cases highly ischemic tubules were brought into perfusion by hyperemia. The distribution of glomerular filtrate to tubular reabsorptive mass (glucose Tm), on the other hand, showed a marked distortion with a tendency for the over-all filtration rate to remain within normal limits, owing to the opposing operation of large numbers of hyperemic and ischemic glomeruli. It is interesting that the earliest, most persistent and most consistent finding in the hypertensive kidney was a reduction in Diodrast Tm, usually considerably in excess of the

glucose Tm. This finding indicates that two activities presumably localized in approximately the same segment of the nephron may be affected differently by the same disease process. Glucose Tm fell only after a considerable change in Diodrast Tm had occurred, and it was thought that this preferential depression of the rate of Diodrast excretion might arise out of an interference by the disease with intracellular metabolic activities and indeed might point to the primary defect in the kidney in essential hypertension.⁶³ In summary, the renal functional picture during the course of essential hypertension seems to be one in which the progressive reduction in Diodrast Tm is associated with a reduction in renal blood flow, little or no change in filtration rate and an elevation in the filtrate fraction, all of which are probably attributable to the hemodynamic factor of increased arteriolar tone (predominantly efferent). There is little alteration in the distribution of blood to each unit of the parenchyma, but a marked distortion in the distribution of filtrate to the tubules, probably again on a hemodynamic basis, so that hyperfiltration in some units balances hypofiltration in others and maintains an over-all filtration rate within normal limits.

Renal functional patterns have not yet been clearly defined in the nephroses. A number of the patients studied by Earle and his co-workers⁶⁹ were examined during the nephrotic stage of glomerulonephritis. There were no distinctive features by which these patients could be distinguished from others suffering from chronic diffuse glomerulonephritis. In nephrotic children, however, it has been known for several years that the urea clearance is increased.¹⁰⁰ The inulin clearance has been found to be elevated as much or more than the urea clearance,¹⁰¹ and during the last year Emerson and Dole¹⁰² reported increases in both inulin and Diodrast clearances with a slight elevation of the filtration fraction. They attribute the supernormal urea clearance to increased renal blood flow.

* * *

Obviously a considerable amount of work remains to be done. Knowledge of functional patterns during chronic Bright's disease is faulty and incomplete. Although many new methods have been developed by which quantitative studies of renal activities may be made, they have found intensive use only in the study of glomerulonephritis and of essential hypertension. Pyelonephritis and the various nephroses await similar investigation. These studies are of the greatest importance from the standpoint of pathogenesis, diagnosis, prognosis and treatment. The discovery that certain functional hallmarks distinguish glomerulonephritis and essential hypertension may find use in differential diagnosis. Further special investigations may reveal facts on which prognostic criteria can be safely established. Elucidation of the etiology of chronic Bright's disease, clarification of the difficult prob-

lems of hypertension and improvement of therapy may result from an intensive examination of tubular intracellular metabolic activity.

NEW HAMPSHIRE MEDICAL SOCIETY

PROCEEDINGS OF THE ONE HUNDRED AND FIFTY-THIRD ANNIVERSARY

House of Delegates, May 15 and 16, 1944 (Continued)

The next report was that of the Committee on Child Health, by Dr. Fairfield, as follows:

We recommend that the infant-care portion of the Emergency Maternal and Child Care Program be accepted under the following conditions:

That major surgical aid not be included, again because of the difficulty in determining who are "qualified consultants."

That medical aid be accepted only for illnesses requiring over two home or office visits. (This plan would eliminate many needless calls on essentially well babies and would eliminate a great deal of extra work involved in applying for aid, authorizing the service and approving the records for payment.)

Dr. Mullins asked whether he was correct in saying that the maternity program was not tied up directly with the maternity program previously voted on. Dr. Atchison replied that the program did not have to be accepted as a whole. The program was termed Emergency Maternity and Infant Care. The infant-care part of it was designed to take care of the sick in the first year of life and was not necessarily connected with the maternity part. But in conference with the Children's Bureau she was led to understand that most states included the infant care, and they had not refused to do so.

Dr. Mullins moved that recommendations of the Maternity and Infancy Committee be accepted. This motion was duly seconded and was carried.

Report of the Committee on the Control of Cancer

Last year this committee stated that the Executive Committee of the Women's Field Army would consider the advisability of using some of the money raised by the Women's Field Army for the encouragement of postgraduate study in cancer control, by offering any of the physicians associated with the New Hampshire cancer clinics an opportunity to take a refresher course. At a subsequent meeting of the committee it was voted to offer \$250 for a month's study in one of the centers where cancer is a major activity. Owing to war conditions the committee thought it advisable to offer the same type of assistance for a shorter period at a proportionate remuneration for two weeks or even one week. The chairman of the committee made arrangements with the Memorial Hospital and the Presbyterian Hospital in New York City and with three hospitals in Boston, whereby contacts could be made with the visiting staffs for clinical observation, surgery and x-ray and radium therapy.

Since January 1, four physicians connected with the New Hampshire clinics have taken advantage of this offer, and all have reported most satisfactory co-operation from these hospitals. More of the forty-five or more physicians associated with the clinics are urged to take advantage of this financial assistance to improve their knowledge of cancer diagnosis and treatment.

The usual three short letters from your committee have been sent to all the physicians in the State. The first one called attention to the importance of blood studies in the diagnosis and treatment of cancer, particularly in patients with tumors of lymph nodes in order to detect the possible presence of leukemia, and also stressed the importance of differentiating anemias from some types of cancer, particu-

larly cancer of the stomach. Attention was also called to the importance of blood studies with special reference to the indication for the need of transfusions in surgery of cancer patients, and in prolonged x-ray therapy. The second letter discussed the diagnostic significance of vaginal bleeding and of the differential diagnosis between carcinoma of the fundus and carcinoma of the cervix, with suggestions for procedures in making the clinical diagnosis. The third letter briefly discussed cancer of the lung with its symptoms, diagnosis and treatment, and emphasized the frequency of cough as an early symptom, the importance of an x-ray film in suggesting disease and the necessity of following this up with bronchoscopy. Copies of all our past letters have been requested by the Virginia Cancer Foundation for use in that state in their program of cancer education among the physicians.

The fourteen diagnostic clinics and treatment centers examined and treated about the same number of patients as in the previous year. Probably most of the patients who need to come for treatment have eventually arrived at one or another clinic, but it has been found that some of them have delayed coming on account of transportation difficulties, and also patients have not been able to return for checkups as frequently as they should for the same reason. It should be borne in mind that the Women's Field Army will, on application, provide some method of transportation for these people.

The Women's Field Army is also distributing the usual number of educational pamphlets, especially during the month of April, which has been designated Cancer Control Month by the Congress of the United States. They also have furnished many indigent patients with cancer dressings that are made up from linen and cotton collected from the public.

The American Society for the Control of Cancer is sponsoring cancer education in secondary schools in a large number of states throughout the country. In co-operation with educational authorities, some type of cancer instruction has been introduced into many high schools and junior high schools. It has been found that not only are young people interested, but their knowledge of cancer as it is taught in the schools, based primarily on courses in biology, is of definite benefit in instructing the older people in their families. It has been found that both students and teachers are interested in this activity, and here in New Hampshire we have found much interest and a definitely favorable response from the showing of cancer films in the high schools.

Your committee would like an expression of approval of cancer education in the secondary schools of this state before it is taken up as a state-wide project with a larger group of school administrators. We also request continued co-operation on the part of all physicians in the State in responding to requests for physical examinations. This is one phase of the work of the Women's Field Army that is stressed constantly in their literature and in the contacts of the workers with other women.

Your committee has spent \$43.40 on printing, stationery and postage. The balance of our \$50 appropriation has been returned to the treasurer. We respectfully request an appropriation of \$50 for the coming year.

GEORGE C. WILKINS, *Chairman*
RALPH E. MILLER
GEORGE F. DWINELL, *Secretary*

Dr. Mullins suggested that the appropriation of \$50 be continued and moved the adoption of this portion of the report of the Committee on Officers' Reports. This motion was duly seconded and carried.

Report of the Committee on Medical Education and Hospitals

The activities of this committee have been necessarily limited. This is due in the first place to the fact that there have been no fellowships offered by the Commonwealth Fund under present war conditions, presumably because there would be so few men with either the age eligibility requirements or the available time.

The committee has collaborated with various regional and national agencies and committees in surveys pertaining to postwar training opportunities that might be available or might be established in the State or the New England area.

The Speakers' Bureau has been used by a few county societies, and this activity is being continued so far as there is a demand.

The only positive activity of the chairman has been the appointment to membership on the Regional Committee of the Wartime Graduate Medical Program. Region No. 1 consists of Maine, New Hampshire, Vermont and Massachusetts. This committee has been actively engaged in the arrangements of programs at the various military stations in the region. These programs have been organized as a result of a survey of the various commanding officers to line up the topics that seem most desirable to them. These meetings have been held at frequent intervals, and once each month a bulletin announcing all meetings is issued. The speakers for these programs have been obtained by this committee. These meetings have been primarily for the men in military service within the district of the meeting, but they have also been open to civilian physicians. It is probable that this program will be continued indefinitely.

JOHN P. BOWLER, Chairman
JAMES W. JAMESON
HERBERT L. TAYLOR

Dr. Mullins moved the adoption of this report. This motion was duly seconded and was carried.

Report of the Committee on Medical Preparedness

The only activity of this committee has been to assist in the relocation of physicians to care for the civilian needs. In two cities attempts have been made to work out plans so that one doctor will be on duty each night. The doctors will take turns in this work, so that the others may secure more sleep.

DEERING G. SMITH, Chairman
Ezra A. Jones
CARLETON R. METCALF

Dr. Mullins moved the adoption of this report. This motion was duly seconded and was carried.

Report of the Committee on Mental and Social Hygiene

New Hampshire has more agencies and, when filled, a larger number on the staff of these agencies in the performance of social and mental hygiene than ever before. The blind and partially blind, the hard of hearing and the deaf all receive attention. The crippled children, the shut-in and the handicapped adults receive attention from a variety of agencies, and some of the activity on their behalf is from voluntary contributions. Through the efforts of our governor, state employees and inmates of state institutions are having x-ray films of the chest for the detection and treatment of tuberculosis.

There are other fields of human misery less well covered. Our state has many intelligent sufferers from chronic arthritis who are poor and unaided. Many of our general hospitals could be relieved of patients much more expeditiously if there were available in the State a number of good and not too expensive convalescent homes. Institutions are not desirable if they can be avoided, but we must depend on other states for the instruction of our blind and deaf, and we have no institution for the care and treatment of patients suffering from epilepsy, of whom there are a large number in our other institutions.

The absorption of the young men and women of the State by war emphasizes to the trained observer the frequency

in the remaining population not only of senile persons but of psychopathic personalities. We know that the number of senile persons in proportion to the population has increased, and it is probable that pathologic personalities are also on the increase. These persons are neither fully insane, feeble-minded or epileptic, but nevertheless they are not normal and it is unfortunate that they receive no recognition but with those with senile dementias are committed to the State Hospital and burden the space intended for the acutely insane.

We have many special agents, but there are very few psychiatric social workers in the State. We are seriously wanting in psychologists, and in our rural districts there are many psychotic persons who with their families would be greatly benefited by a little special psychiatric advice.

To use the numerous mental tests for the diagnosis of mental deficiency and derangements there should be several psychologists available to the school departments, and in the near future some competent analyzers of human aptitudes are needed to aid in the educational field and rehabilitation. An amount of this work, relatively small in comparison with the needs, has been furnished by the colleges, by the Laconia State School and principally by the State Hospital. The performance of this work calls for support from some source, and it may be properly questioned whether or not state institutions and colleges should be the source of this support, or whether clinics should be publicly maintained.

The sensible publicity approach to venereal disease has been highly advantageous, and we believe that its treatment is much more general and effective than it was some years ago. So far as we can learn, the law requiring blood examination before marriage is properly complied with and fairly efficiently. The law permitting sterilization of the insane, feeble minded and epileptic in institutions is operating conservatively, and we hope in conformity with the letter of the law, which permits operation in hereditary and transmissible cases.

Unknown to many, the State has a law that was intended to limit the marriage of defective persons and is found in Chapter 286 on page 1164 of Volume II of the Public Laws of 1926. As near as we can learn, this law is practically ignored. A few clerks have refused licenses and referred the parties to the State Board of Health for an examination. Under this law it is the duty of all superintendents of schools and all having charge of instruction in private schools and state institutions to report the names of all defectives discharged through those sources. The intention of the law is that the names of those persons be kept on file in the Bureau of Vital Statistics and be available there not only for reference by city clerks but as accumulating data on the number of such persons in the State and for the detection of hereditary families. It is not evident that this part of the law is complied with. There are now 700 inmates at Laconia State School and this is probably not more than 12 per cent of the mentally deficient in the State. We have compiled for years vital statistics, but no one knows how many mentally deficient there are in New Hampshire.

B. W. BAKER, Chairman
CHARLES H. DOLLOFF
JOHN B. McKENNA

Dr. Mullins for the Committee on Officers' Reports agreed that there is a need for more specialized workers in mental and social hygiene in this state, and that proper presentations should be made through the appropriate channels to the State Legislative Assembly in 1945. He moved the adoption of this portion of the Report of the Committee on Officers' Reports. The motion was duly seconded and was carried.

Report of the Committee on Public Health

This, the third year of this committee, has been uneventful. In spite of the increase in activity in industrial fields throughout New England, we of New Hampshire have experienced proportionately a very small increase in man-

r along industrial lines, and this is particularly true e eliminates the Portsmouth area, where so many citi- have been employed in the Portsmouth Navy Yard, her with the lumber centers in the northern section of state. For this reason, the industrial public-health tion in New Hampshire has presented a very minor lem as compared with that in some of the more active rs of manufacture in other sections of the country. e housing situation in and around Portsmouth has ed some anxiety, but this has been greatly relieved by daily transportation of employees to and from their work. : a result of the previous programs of the Committee ublic Health, we feel that the groundwork of this com- ee is well established. We believe that the health of trial employees in this state ranks high and that the dards under which the employees work and live are ng the best. This is substantiated to a large degree by minimum number of absentee records among the em- ees, and this takes into consideration the fact that some e employees travel many miles a day to and from their e of employment and also that the average age of em- ees has increased owing to the drafting of the younger

our committee has had no reference from either em- ers, employees or other sources during the entire year, this again speaks well for our working conditions and th standards, and accounts for the inaction of this mittee.

e have received regular communications in connection i industrial hygiene as published by the United States lic Health Service, together with outlines of programs a various industrial centers.

Unfortunately, your chairman was unable to attend the h Annual Congress on Industrial Health, which was held Chicago in February of this year, owing to the uncer- tity of family affairs at that time, and as yet we have not ived the proceedings of this meeting, so consequently unable to give you the particulars at this writing.

n submitting this report, may we state that it has been a sure to serve on the Committee on Public Health of the e Hampshire Medical Society and, although the duties e been somewhat limited, we feel certain that there will more and more problems presented to this committee time goes on.

HARRIS E. POWERS, *Chairman*
ANTHONY E. PETERS
CLINTON R. MELLIN

Dr. Mullins said that the Committee on Officers' ports was pleased to note the high standard of ublic health in New Hampshire. The fact that complaints have been voiced was a good in- ation that conditions were satisfactory. He ved the adoption of this report. This motion is duly seconded and was carried.

Report of the Committee on Tuberculosis

It is with deep regret that the Committee on Tuberculosis rds in this report the death on March 30, 1944, of one of members, Dr. Clarence O. Coburn, of Manchester. r thirty-eight years Dr. Coburn had been engaged in the ivate practice of medicine in his native city. He had ded his practice to internal medicine, in which field he was dely recognized for his unusual skill, judgment and re- urcefulness. A tried and true physician, Dr. Coburn was all times one who exemplified the finest ideals in citizen- ip and service to his fellow men. During the years 1919 to 21 he was president of the New Hampshire Tuberculosis ssociation. His active interest and support in the campaign ainst the disease was maintained until the end. His death a sad and severe loss to this Society and particularly to the ommittee on Tuberculosis.

As has been stated in previous reports, the encouraging gress that has been made in combating tuberculosis in ew Hampshire is due largely to the efforts of the members e New Hampshire Medical Society. The physicians of ew Hampshire are the first line of defense and attack in e fight against the disease. They are the "case finders" par

excellence in the program of early diagnosis, particularly of open cases, in which prompt supervision and treatment are of utmost importance.

During the past year a larger number of possible tuber- culous patients than for some years past have been referred to the chest diagnostic clinics maintained throughout the State. It is felt that these clinics perform their greatest service when they assist the members of the New Hampshire Medical Society in the diagnosis of tuberculosis among their patients who present suspicious signs and symptoms.

An excellent piece of tuberculosis case finding continues to be carried on at the Selective Service induction center in Manchester. An essential part of the exacting examinations at this induction center is an x-ray examination of the chest for every man. All men found to have roentgenographic evidence of tuberculosis are afforded prompt follow-up. In this way, the Selective Service Boards are not only keeping tuberculosis out of the military forces but are also providing a splendid case-finding program for a sizable segment of the population of our state.

Since June, 1943, the chests of approximately 4500 workers in the industries of this state have been examined roentgeno- graphically. This has been accomplished through a joint program inaugurated and maintained by the Industrial Hygiene Division of the State Department of Health and the New Hampshire Tuberculosis Association. The remarkable success of this program is due to the whole-hearted co- operation of management and labor, including industrial physicians and labor organizations. This program is resulting in the discovery of large numbers of potentially active cases of tuberculosis. The program is progressing rapidly.

For some years your committee has emphasized the great value of the chest roentgenogram in the discovery of tuber- culous patients. It is well known that tuberculous lesions can be seen in the chest roentgenographically before signs can be heard with the stethoscope. We again urge the mem- bers of the New Hampshire Medical Society to use the roentgenographic method frequently when examining chests. The New Hampshire Tuberculosis Association is ready to provide chest x-ray films for persons referred by physicians when these persons are unable to pay for them. Furthermore, the New Hampshire State Sanatorium and the New Hamp- shire Tuberculosis Association continue to offer their services in the interpretation of chest x-ray films sent to them for diagnosis.

We also urge prompt examination of all members of the family when a case of tuberculosis is found, since in a house- hold where an open case has been discovered we usually find that all members are positive tuberculin reactors.

We also urge at least a tuberculin test for all persons car- ing for children. This should be a routine procedure for nursemaids, governesses and others in contact with children.

In the treatment of tuberculosis, bed rest continues to be emphasized. It is generally considered that a bed-rest regime is extremely helpful in deciding on the clinical activity of the disease. Surgical procedures such as pneumothorax phreni- cotomy, phrenicotomy and thoracoplasty are still employed in properly selected cases as aids to the cure of the disease.

Beginning July 1, 1943, the appropriation for hospitaliza- tion of tuberculosis cases under the advanced case appropria- tion was transferred from the State Department of Public Welfare to the State Department of Health. Applications for admission of patients to the Pembroke Sanatorium are now sent to the State Department of Health. The medical supervision of the patients at the Pembroke Sanatorium is therefore under the jurisdiction of the State Department of Health.

Dr. Rufus R. Little, superintendent and medical director of the New Hampshire State Sanatorium at Glenciff, has been appointed consultant on tuberculosis to the State Department of Health. This program has proved extremely helpful, and the work of the two sanatoriums is now splen- didly co-ordinated. Dr. Little visits the Pembroke Sanato- rium once a week. Once in three weeks, chest surgery is per- formed at the Glenciff Sanatorium for patients from both institutions. These operations comprise thoracoplasty, lobectomy, phrenicectomy and so forth. Pneumothorax is a routine procedure at both sanatoriums.

Our nation is now in the final stages of the second great war. It appears that up to the present time there has been no in- crease in the number of deaths or the death rate from tuber- culosis in New Hampshire. The number of *known* cases has

Report of the Committee on Medical Education and Hospitals

The activities of this committee have been necessarily limited. This is due in the first place to the fact that there have been no fellowships offered by the Commonwealth Fund under present war conditions, presumably because there would be so few men with either the age eligibility requirements or the available time.

The committee has collaborated with various regional and national agencies and committees in surveys pertaining to postwar training opportunities that might be available or might be established in the State or the New England area.

The Speakers' Bureau has been used by a few county societies, and this activity is being continued so far as there is a demand.

The only positive activity of the chairman has been the appointment to membership on the Regional Committee of the Wartime Graduate Medical Program. Region No. 1 consists of Maine, New Hampshire, Vermont and Massachusetts. This committee has been actively engaged in the arrangements of programs at the various military stations in the region. These programs have been organized as a result of a survey of the various commanding officers to line up the topics that seem most desirable to them. These meetings have been held at frequent intervals, and once each month a bulletin announcing all meetings is issued. The speakers for these programs have been obtained by this committee. These meetings have been primarily for the men in military service within the district of the meeting, but they have also been open to civilian physicians. It is probable that this program will be continued indefinitely.

JOHN P. BOWLER, *Chairman*
JAMES W. JAMESON
HERBERT L. TAYLOR

Dr. Mullins moved the adoption of this report. This motion was duly seconded and was carried.

Report of the Committee on Medical Preparedness

The only activity of this committee has been to assist in the relocation of physicians to care for the civilian needs. In two cities attempts have been made to work out plans so that one doctor will be on duty each night. The doctors will take turns in this work, so that the others may secure more sleep.

DEERING G. SMITH, *Chairman*
EZRA A. JONES
CARLETON R. METCALF

Dr. Mullins moved the adoption of this report. This motion was duly seconded and was carried.

Report of the Committee on Mental and Social Hygiene

New Hampshire has more agencies and, when filled, a larger number on the staff of these agencies in the performance of social and mental hygiene than ever before. The blind and partially blind, the hard of hearing and the deaf all receive attention. The crippled children, the shut-in and the handicapped adults receive attention from a variety of agencies, and some of the activity on their behalf is from voluntary contributions. Through the efforts of our governor, state employees and inmates of state institutions are having x-ray films of the chest for the detection and treatment of tuberculosis.

There are other fields of human misery less well covered. Our state has many intelligent sufferers from chronic arthritis who are poor and unaided. Many of our general hospitals could be relieved of patients much more expeditiously if there were available in the State a number of good and not too expensive convalescent homes. Institutions are not desirable if they can be avoided, but we must depend on other states for the instruction of our blind and deaf, and we have no institution for the care and treatment of patients suffering from epilepsy, of whom there are a large number in our other institutions.

The absorption of the young men and women of the State by war emphasizes to the trained observer the frequency

in the remaining population not only of senile persons but of psychopathic personalities. We know that the number of senile persons in proportion to the population has increased, and it is probable that pathologic personalities are also on the increase. These persons are neither fully insane, feeble-minded or epileptic, but nevertheless they are not normal and it is unfortunate that they receive no recognition but with those with senile dementias are committed to the State Hospital and burden the space intended for the acutely insane.

We have many special agents, but there are very few psychiatric social workers in the State. We are seriously wanting in psychologists, and in our rural districts there are many psychotic persons who with their families would be greatly benefited by a little special psychiatric advice.

To use the numerous mental tests for the diagnosis of mental deficiency and derangements there should be several psychologists available to the school departments, and in the near future some competent analyzers of human aptitudes are needed to aid in the educational field and rehabilitation. An amount of this work, relatively small in comparison with the needs, has been furnished by the colleges, by the Laconia State School and principally by the State Hospital. The performance of this work calls for support from some source, and it may be properly questioned whether or not state institutions and colleges should be the source of this support, or whether clinics should be publicly maintained.

The sensible publicity approach to venereal disease has been highly advantageous, and we believe that its treatment is much more general and effective than it was some years ago. So far as we can learn, the law requiring blood examination before marriage is properly complied with and fairly efficiently. The law permitting sterilization of the insane, feeble minded and epileptic in institutions is operating conservatively, and we hope in conformity with the letter of the law, which permits operation in hereditary and transmissible cases.

Unknown to many, the State has a law that was intended to limit the marriage of defective persons and is found in Chapter 286 on page 1164 of Volume II of the Public Laws of 1926. As near as we can learn, this law is practically ignored. A few clerks have refused licenses and referred the parties to the State Board of Health for an examination. Under this law it is the duty of all superintendents of schools and all having charge of instruction in private schools and state institutions to report the names of all defectives discharged through those sources. The intention of the law is that the names of those persons be kept on file in the Bureau of Vital Statistics and be available there not only for reference by city clerks but as accumulating data on the number of such persons in the State and for the detection of hereditary families. It is not evident that this part of the law is complied with. There are now 700 inmates at Laconia State School and this is probably not more than 12 per cent of the mentally deficient in the State. We have compiled for years vital statistics, but no one knows how many mentally deficient there are in New Hampshire.

B. W. BAKER, *Chairman*
CHARLES H. DOLLOFF
JOHN B. MCKENNA

Dr. Mullins for the Committee on Officers' Reports agreed that there is a need for more specialized workers in mental and social hygiene in this state, and that proper presentations should be made through the appropriate channels to the State Legislative Assembly in 1945. He moved the adoption of this portion of the Report of the Committee on Officers' Reports. The motion was duly seconded and was carried.

Report of the Committee on Public Health

This, the third year of this committee, has been uneventful. In spite of the increase in activity in industrial fields throughout New England, we of New Hampshire have experienced proportionately a very small increase in man-

power along industrial lines, and this is particularly true in the Portsmouth area, where so many citizens have been employed in the Portsmouth Navy Yard, together with the lumber centers in the northern section of our state. For this reason, the industrial public-health situation in New Hampshire has presented a very minor problem as compared with that in some of the more active centers of manufacture in other sections of the country.

The housing situation in and around Portsmouth has caused some anxiety, but this has been greatly relieved by the daily transportation of employees to and from their work.

As a result of the previous programs of the Committee on Public Health, we feel that the groundwork of this committee is well established. We believe that the health of industrial employees in this state ranks high and that the standards under which the employees work and live are among the best. This is substantiated to a large degree by the minimum number of absentee records among the employees, and this takes into consideration the fact that some of the employees travel many miles a day to and from their place of employment and also that the average age of employees has increased owing to the drafting of the younger men.

Your committee has had no reference from either employers, employees or other sources during the entire year, and this again speaks well for our working conditions and health standards, and accounts for the inaction of this committee.

We have received regular communications in connection with industrial hygiene as published by the United States Public Health Service, together with outlines of programs from various industrial centers.

Unfortunately, your chairman was unable to attend the Sixth Annual Congress on Industrial Health, which was held in Chicago in February of this year, owing to the uncertainty of family affairs at that time, and as yet we have not received the proceedings of this meeting, so consequently are unable to give you the particulars at this writing.

In submitting this report, may we state that it has been a pleasure to serve on the Committee on Public Health of the New Hampshire Medical Society and, although the duties have been somewhat limited, we feel certain that there will be more and more problems presented to this committee as time goes on.

HARRIS E. POWERS, *Chairman*
ANTHONY E. PETERS
CLINTON R. MELLIN

Dr. Mullins said that the Committee on Officers' Reports was pleased to note the high standard of public health in New Hampshire. The fact that no complaints have been voiced was a good indication that conditions were satisfactory. He moved the adoption of this report. This motion was duly seconded and was carried.

Report of the Committee on Tuberculosis

It is with deep regret that the Committee on Tuberculosis records in this report the death on March 30, 1944, of one of its members, Dr. Clarence O. Coburn, of Manchester. For thirty-eight years Dr. Coburn had been engaged in the private practice of medicine in his native city. He had devoted his practice to internal medicine, in which field he was widely recognized for his unusual skill, judgment and resourcefulness. A tried and true physician, Dr. Coburn was at all times one who exemplified the finest ideals in citizenship and service to his fellow men. During the years 1919 to 1921 he was president of the New Hampshire Tuberculosis Association. His active interest and support in the campaign against the disease was maintained until the end. His death is a sad and severe loss to this Society and particularly to the Committee on Tuberculosis.

As has been stated in previous reports, the encouraging progress that has been made in combating tuberculosis in New Hampshire is due largely to the efforts of the members of the New Hampshire Medical Society. The physicians of New Hampshire are the first line of defense and attack in the fight against the disease. They are the "case finders" par

excellence in the program of early diagnosis, particularly of open cases, in which prompt supervision and treatment are of utmost importance.

During the past year a larger number of possible tuberculous patients than for some years past have been referred to the chest diagnostic clinics maintained throughout the State. It is felt that these clinics perform their greatest service when they assist the members of the New Hampshire Medical Society in the diagnosis of tuberculosis among their patients who present suspicious signs and symptoms.

An excellent piece of tuberculosis case finding continues to be carried on at the Selective Service induction center in Manchester. An essential part of the exacting examinations at this induction center is an x-ray examination of the chest for every man. All men found to have roentgenographic evidence of tuberculosis are afforded prompt follow-up. In this way, the Selective Service Boards are not only keeping tuberculosis out of the military forces but are also providing a splendid case-finding program for a sizable segment of the population of our state.

Since June, 1943, the chests of approximately 4500 workers in the industries of this state have been examined roentgenographically. This has been accomplished through a joint program inaugurated and maintained by the Industrial Hygiene Division of the State Department of Health and the New Hampshire Tuberculosis Association. The remarkable success of this program is due to the whole-hearted cooperation of management and labor, including industrial physicians and labor organizations. This program is resulting in the discovery of large numbers of potentially active cases of tuberculosis. The program is progressing rapidly.

For some years your committee has emphasized the great value of the chest roentgenogram in the discovery of tuberculous patients. It is well known that tuberculous lesions can be seen in the chest roentgenographically before signs can be heard with the stethoscope. We again urge the members of the New Hampshire Medical Society to use the roentgenographic method frequently when examining chests. The New Hampshire Tuberculosis Association is ready to provide chest x-ray films for persons referred by physicians when these persons are unable to pay for them. Furthermore, the New Hampshire State Sanatorium and the New Hampshire Tuberculosis Association continue to offer their services in the interpretation of chest x-ray films sent to them for diagnosis.

We also urge prompt examination of all members of the family when a case of tuberculosis is found, since in a household where an open case has been discovered we usually find that all members are positive tuberculin reactors.

We also urge at least a tuberculin test for all persons caring for children. This should be a routine procedure for nursemaids, governesses and others in contact with children.

In the treatment of tuberculosis, bed rest continues to be emphasized. It is generally considered that a bed-rest regime is extremely helpful in deciding on the clinical activity of the disease. Surgical procedures such as pneumothorax phrenicotomy, phrenicotomy and thoracoplasty are still employed in properly selected cases as aids to the cure of the disease.

Beginning July 1, 1943, the appropriation for hospitalization of tuberculosis cases under the advanced case appropriation was transferred from the State Department of Public Welfare to the State Department of Health. Applications for admission of patients to the Pembroke Sanatorium are now sent to the State Department of Health. The medical supervision of the patients at the Pembroke Sanatorium is therefore under the jurisdiction of the State Department of Health.

Dr. Rufus R. Little, superintendent and medical director of the New Hampshire State Sanatorium at Glencliff, has been appointed consultant on tuberculosis to the State Department of Health. This program has proved extremely helpful, and the work of the two sanatoriums is now splendidly co-ordinated. Dr. Little visits the Pembroke Sanatorium once a week. Once in three weeks, chest surgery is performed at the Glencliff Sanatorium for patients from both institutions. These operations comprise thoracoplasty, lobectomy, phrenicectomy and so forth. Pneumothorax is a routine procedure at both sanatoriums.

Our nation is now in the final stages of the second great war. It appears that up to the present time there has been no increase in the number of deaths or the death rate from tuberculosis in New Hampshire. The number of *known* cases has

increased, but not the *known active*—so-called “open”—cases of tuberculosis. Because of the careful x-ray chest surveys at the Induction Center by the War Department, and among workers in industry by the State Department of Health and the New Hampshire Tuberculosis Association, a definite increase in known tuberculosis cases has been recorded. Although these cases are mostly in the arrested stage, they nevertheless constitute a potentially active source of the disease. The necessity for proper medical advice and supervision in such cases is obvious.

The fact remains that tuberculosis and war are still allies. Infection with tubercle bacilli is still widespread among the people. Tuberculin-test surveys indicate that approximately 50 per cent of the adult population of our state harbor tubercle bacilli. The infection is held in abeyance in many cases because of adequate physical resistance on the part of those who are infected. Longer hours of labor and increased mental and physical strain tend to lower physical resistance, thereby predisposing toward the breakdown of a previously quiescent or so-called “healed” lesion. To use the layman’s words, tired bodies may permit the ever-lurking tuberculosis germs to attack the lung cells successfully.

There must be no relaxation in the fight against the tubercle bacillus. In fact, the fight must be carried on with ever greater aggressiveness to hold the gains won.

Your committee avails itself of this opportunity to express its deep sense of gratitude and appreciation for the wholehearted assistance and encouragement accorded to it by the members of the New Hampshire Medical Society.

ROBERT B. KERR, *Chairman*
RICHARD C. BATT

Dr. Mullins for the Committee on Officers’ Reports congratulated the Committee on Tuberculosis on its excellent and inclusive report. The change of administration from the Department of Public Welfare to that of Public Health seemed to him a proper step. The suggestion of more frequent use of the x-ray in suspected cases of tuberculosis was particularly commended. Dr. Mullins moved the adoption of this report, and the motion was duly seconded and was carried.

Report of the Delegate to the House of Delegates of the American Medical Association

The annual session of the American Medical Association was held at Chicago, June 7, 8 and 9, 1943, and was limited to meetings of the House of Delegates and to two general meetings. Your delegate served as chairman of the Reference Committee on Reports of Officers. He has endeavored to select the high points of the meeting for this report to the New Hampshire Medical Society.

Elliott P. Joslin, of Boston, was given the Distinguished Service Award and Herman I. Kretschmer, of Chicago, was chosen president-elect.

The Committee on Planning of Postwar Medical Services was established, to co-operate and collaborate with other agencies concerned with these problems.

The Board of Trustees made a lengthy report dealing with hospital corporations engaging in the practice of medicine. That the Blue Cross plans to give medical service with or without the approval of the medical profession there can be no doubt after reading this report. It was voted that hospitals should not be permitted to practice medicine, and the House reiterated its disapproval of the injecting of a third party into the personal relation of the patient and the physician. It further voted “that the practice of radiology, pathology and anesthesiology is the practice of medicine just as much as is the practice of surgery or internal medicine, and that it is only a short step from including the first three in a medical-service plan to including the whole field of medicine in such a plan.”

The Council on Medical Service and Public Relations was established. The functions of this council are as follows: to make available facts, data and medical opinions with respect to timely and adequate rendition of medical care to

the American people; to inform constituent associations and component societies of proposed changes affecting medical care in the nation; to inform constituent associations and component societies regarding the activities of the council; to investigate matters pertaining to the economic, social and similar aspects of medical care for all the people; to study and suggest means for the distribution of medical service to the public consistent with the principles adopted by the House of Delegates; to develop and assist committees on medical service and public relations originating within the constituent associations and component societies of the American Medical Association.

The action of the federal government in making funds available for maternity and infant care for the wives and infants of enlisted men was approved, and adoption was urged of a plan under which the federal government would provide for the wives of enlisted men a stated allotment for medical, hospital, maternity and infant care similar to the allotments already provided for the maintenance of dependents, leaving the actual arrangements with respect to fees to be fixed by mutual agreement with the wife and the physician of her choice. This action was similar to that taken by the New Hampshire House of Delegates last May. A copy of the resolution urging that the method of making available these funds be changed to an allotment basis was sent to each congressman and each senator. (After considerable discussion in the House of Representatives, the proposal was rejected by a vote of 115 to 8.)

The Board of Trustees, in its report devoted considerable space to the subject of prepaid medical service. It gave the history of the various plans and discussed the progress that had been made under them. This report was published in the April 24, 1943, issue of the *Journal of the American Medical Association*. In view of the present discussion of a prepayment medical plan in our state, it seems advisable to point out some of the dangers and complications of such a plan. These were first included in a special report, approved by the House of Delegates in 1935, and seem no less applicable today than at that time; they are as follows:

The adoption and operation of a medical plan where it is unnecessary.

The stimulus aroused by good plans among irresponsible organizers to develop and operate imitations and counterfeits.

The establishment in medical practice of dangerous patterns, following the adoption of undesirable types of plans.

The compromise of medical societies in the corporate practice of medicine or in the operation of insurance companies as a result of an insufficient study of state statutes and case law.

Failure, in the operation of a plan, to conform to the *Principles of Medical Ethics*.

The almost inevitable transition of voluntary insurance plans into compulsory contributory sickness insurance systems operated by the state.

The difficulties involved in the failure adequately to provide for complete control of medical affairs by the medical profession.

The “freezing” of medical fees at a point below that which is consistent with good medical care.

Failure to bear constantly in mind that a medical society plan is an experiment in the methods of distributing medical service and that it may have only a temporary usefulness, may need frequent or drastic modifications or may need to be discarded entirely.

Medical society plans must not be considered or accepted as a substitute for the regular practice of medicine as applied to the majority of people. If it is believed such plans may be useful, they should be considered merely as supplementary facilities in the distribution of medical service. They should be used only so long and in such a manner as they serve efficiently to make more easily available to low-income groups a high quality of medical care.

The April 29, 1944, issue of the *Journal of the American Medical Association* contains the report of the Board of Trustees for the past year. It is stated there: “The population group that has incomes too small to meet health necessities in the way of food, clothing, fuel and shelter cannot be expected to budget or make prepayments for catastrophic

These 'medically indigent' are always more of an economic than of a medical problem, since their medical care, regardless of the manner by which the cost is met, must, as always, be paid for directly or indirectly out of higher incomes." The necessary legislation has been secured and administrative organizations for the operation of prepayment plans are functioning in 14 states, and some part of the program has been undertaken in ten additional states. These plans have been in operation from a few months to seven years, but the demand for the service is apparently slight, with the exception of Michigan a very small proportion of the population is enrolled. The figures given are as of 1933, in most instances the latter part of the year: California, 88,000; Colorado, 5,000; Massachusetts, 23,000; Michigan, 600,455; Missouri and Kansas, 6,500; New Jersey, 100,000; New York, 17,000 (with 22,000 in a second plan, and 30,000 in a third plan); North Carolina, 13,031; Pennsylvania, 10,000; and Texas, 378. It is evident that prepayment medical plans are still in the experimental stage, and it seems as if the

New Hampshire Medical Society should consider further the advisability of launching its plan at this time.

DEERING G. SMITH

Dr. Mullins for the Committee on Officers' Reports expressed indebtedness to Dr. Smith for a thought-provoking summary of the actions of the American Medical Association. He added that consideration of these facts should guide the Society in its decisions regarding the various programs being instituted by the federal government. He moved the adoption of this report. This motion was duly seconded and was carried.

CASE 30391

PRESENTATION OF CASE

A fifty-nine-year-old engineering executive was seen at home because of difficulty in breathing. The patient had always been active. While in college he had a tendency to have rapid or irregular heart action, which occasioned interest but did not bother him. At the age of forty, however, after a sleep, he was seized by his first attack of palpitation. The heart action was forceful and rapid, and the attack lasted for half an hour after dinner. Since then he had had a great deal of palpitation, mostly jumps or skips but occasionally spells of heart racing (usually regular). The palpitation was especially apparent when he was tired and at rest. Examination of the heart during these attacks showed extrasystoles. The blood pressure was 135 systolic, 80 diastolic. An electrocardiogram at the age of forty-eight showed a normal rhythm with a rate of 92. The PR interval was 0.20 second, the RS interval 0.06 second, and the T waves upright in all leads; the axis was normal. The following year he had an attack of ureteral colic on the right. The heart sounds at that time were poor. There was a definite third sound, as well as gallop rhythm, which was marked in the upright position. The blood

*On leave of absence.

pressure was 150 systolic, 100 diastolic. An electrocardiogram a year later showed a normal rhythm with a rate of 100, a PR interval of 0.24 second, slight left-axis deviation and frequent premature ventricular beats. These findings persisted for the next two years. There was no pain at any time. Two years later a slight presystolic gallop rhythm was heard at the apex. Frequent premature beats were present. The blood pressure was 160 systolic, 100 diastolic. At another examination he had a bigeminal pulse. The heart rhythm was definitely coupled with an extrasystole every other beat. The blood pressure was 150 systolic, 85 diastolic. An electrocardiogram showed normal sinus rhythm, a rate of 94, a PR interval of 0.24 second and a QRS interval of 0.08 second. T₁ and T₂ were low, and T₃ upright. There was slight shift of the axis to the right. Ventricular extrasystoles were present throughout the record, giving it a bigeminal rhythm. He was given potassium iodide for two or three months, with rest, and felt much better. The heart was regular and rapid. When fifty-five years old he had lobar pneumonia. He was hospitalized for three weeks, and during this illness "his heart did beautifully." A gallop rhythm or third sound persisted. The blood pressure was 120 systolic, 80 diastolic. Six months later he experienced irregularity of the heart beat associated with a desire to take a deep breath. He was given 0.2 gm. of quinidine twice a day for ten days, with definite benefit, but he was then hospitalized.

Examination on admission showed slight cyanosis. The left border of cardiac dullness was 14 cm. to the left of the midline. The heart was rapid but regular. The sounds were of poor quality. There was pulsus alternans, with a marked protodiastolic gallop at the apex. The pulmonic second sound was greater than the aortic. There were wheezes throughout both lung fields, with medium moist rales at the right base. The blood pressure was 145 systolic, 95 diastolic. The blood counts were normal. The

basal metabolic rate was normal. An electrocardiogram revealed ventricular premature beats interrupting sinoauricular tachycardia at a rate of 115. There was slight auriculoventricular block, with a PR interval of 0.22 second. The QRS waves

cardiogram (Fig. 1) showed a PR interval of 0.3 second, a rate of 90, slight inversion of T_1 , T_2 and T_4 , and slurred QRS complexes in Leads 1, 2 and 3; there was an increase in voltage over the previous records. His condition steadily improved until the

FIGURE 1.

were of low voltage, slurred and slightly widened. The T waves were low in all four leads.

The patient was given aminophyllin and sedatives as desired. After two weeks of bed rest he showed a rising pulse rate (130), persistent rales in both lungs and, *except when taking aminophyllin*, Cheyne-Stokes respirations. He was given 0.4 gm. of digitalis for four days and then 0.03 gm. daily. At the end of that period he woke up early one morning with a dull ache in the right groin which extended down to the knee and lasted for several hours. The leg seemed to buckle under him. Examination of the leg was negative. An electro-

twenty-eighth hospital day, when, on moving, he suddenly had a sharp, stabbing, fleeting, nonradiating pain in the left anterior chest without interference to breathing. On questioning, he stated that he had experienced a similar pain in the right chest the previous night. Examination was negative except for a presystolic and a protodiastolic gallop. The heart sounds were of very poor quality; the second sound was almost inaudible. The blood pressure was 135 systolic, 90 diastolic. In the next ten days his condition improved considerably. the gallop rhythm became hardly noticeable,

he was discharged on the forty-sixth hospital

the course of the next three and a half years it well, although he became fatigued rather and was conscious of the irregularities of heart beat and breathing. On such occasions a p rhythm was present. At all other times, the i was rapid but regular, the sounds were of quality, and there were no murmurs. Distended veins were occasionally seen. During most of period he received digitalis, phenobarbital and butal.

Following a severe upper respiratory infection which he slowly recovered, he developed pneumonia and Cheyne-Stokes breathing at night. There was pulsus alternans, and the heart rate was 115. The blood pressure was 115 systolic, 80 diastolic. He was further digitalized. Nocturnal pneumonia and Cheyne-Stokes breathing disappeared about two weeks. The pulsus alternans could not be heard, but there were four definite sounds in the heart. The pulse, however, remained high. He continued to take 0.03 gm. of digitalis daily. It was decided that he should retire from his business.

The next month, following the emotional strain of selling his home and closing his business, he again developed nocturnal Cheyne-Stokes breathing. Examination showed slight dyspnea. The pulse was normal at 108. The blood pressure was 150 systolic, 100 diastolic, with evidence of pulsus alternans. Both arterial and venous pulsations were slightly increased in the neck. The cardiac impulse was felt 4 cm. to the left of the midsternal line in the sixth intercostal space. Marked diastolic gallop rhythm was present. A slight apical systolic murmur was heard. The pulmonic second sound was increased. The lungs were clear except for persistent fine rales at both bases. The liver was palpable two finger-breadths below the costal margin but was not tender. There was no edema. The patient was given 1 cc. of Salyrgan, and the fluid intake was limited to 1200 cc. There was good diuresis. Cheyne-Stokes breathing continued, however, and one week later basal rales were again heard. He was given 1 cc. of Salyrgan and theophyllin intravenously every fourth day, and 0.2 gm. of aminophyllin after each meal. He improved considerably during the next ten days. The following morning he awoke and was unable to speak clearly, to feed himself or to recognize simple objects, such as a fork and a spoon, or what to do with them. He was, however, conscious of his disability, a little agitated and somewhat confused. Neurologic examination a few hours later, during which time he had improved considerably, showed much difficulty in co-ordination and in use of the right arm and, to a less extent, of the right leg, without any particular weakness. The reflexes of the right arm and leg were slightly

more active. The abdominal reflexes were absent on the right. The plantar reflexes were normal. No sensory disturbances could be made out, but there was definite stereognosis, more on the right than on the left. The cardiac situation was about the same, with the rate about 100.

During the course of the next five days the neurologic symptoms improved, and in the following two days he had nausea and retching without pain or fever. Digitalis was stopped. Examination of the heart showed galloping, with a slight apical systolic murmur. The sounds were weak, and the rate was 110, with slight pulsus alternans and occasional premature beats. The blood pressure was 140 systolic, 100 diastolic. The lungs were clear. He was placed in an oxygen tent. He became restless and developed marked cyanosis, the Cheyne-Stokes breathing increased, with periods of apnea lasting forty to sixty seconds, and he died four days later.

DIFFERENTIAL DIAGNOSIS

DR. CONGER WILLIAMS: So far in discussing these cases I have had a perfect score — 100 per cent wrong. I am sure that this case will be no exception.

Up to ten years before the final episode, this man had had no definite evidence of heart disease. It is true that he had had numerous episodes of palpitation and possibly even paroxysmal tachycardia of unknown kind, but as everyone knows, that is a frequent finding with a normal heart. I am sure that up to that time he had had no significant heart disease.

"The PR interval was 0.24 second." In that statement lies the answer to the gallop rhythm. Gallop rhythm may or may not have a serious prognostic significance. If the gallop is the result of a weakened myocardium, it may be extremely important. On the other hand, it is well to remember that in the presence of a long PR interval the distance between auricular and ventricular contraction is increased and therefore it is often possible to hear the auricular sound as a separate sound, in which event gallop rhythm is produced. That is undoubtedly the case here because the rhythm lasted ten years, and it is unusual to have gallop rhythm due to myocardial weakness last that long. At that time there occurred the first evidence of disease of the cardiovascular system, in that he was developing hypertension and evidence of auriculo-ventricular block.

"At another examination he had a bigeminal pulse." This finding is not necessarily significant since we know that he had been subject to ectopic beats most of his life.

The electrocardiogram taken at the age of fifty-one was abnormal in that T₁ and T₂ were low. I do

not believe that the slight shift in axis to the right was significant.

I presume that the potassium iodide was given for arteriosclerosis rather than for syphilis or goiter. Whether quinidine was given to cut down on the number of ectopic beats, or whether he actually had a paroxysmal arrhythmia, such as fibrillation, I cannot say from the evidence.

The finding of pulsus alternans at the age of fifty-five was really the first definite evidence of myocardial weakness. It is an important finding as a rule, and in this case had special significance because the gallop rhythm during the first few years of observation was not the result of a weakened myocardium.

The rising pulse and the lung findings may have represented increase in cardiac failure in spite of the fact that he was kept at bed rest and given treatment. I do not know why the giving of digitalis was delayed so long unless it was thought that the lung findings were due to something else.

The cause of the attack of pain in the right leg is not apparent. He might have had thrombophlebitis giving a transitory episode of pain or possibly a small arterial embolus from the heart that set up generalized vasospasm, a not uncommon occurrence; it is possible for such a small embolus to break up subsequently and to be distributed throughout the vascular tree, leaving no evidence of arterial occlusion on subsequent physical examination.

I presume that the pain in the anterior chest was not related to breathing. The fact that he had had similar pain on the previous night, however, is evidence in favor of the diagnosis of thrombophlebitis. This might well have represented a small pulmonary embolus first to the right lung and then to the left. He had been in bed for at least two weeks before this happened, and the pulmonary episode apparently followed the development of pain in the leg. It is also possible that the dyspnea at the time of admission and the finding of rales at both lung bases represented an earlier pulmonary embolus.

It is obvious that toward the end he had some sort of destructive lesion involving the left side of the brain. It could have been an embolus but most likely was a thrombus or hemorrhage. The sudden onset and the rather rapid clearing are in favor of a vascular episode.

A few things are fairly certain. We have a patient, fifty-nine years of age, who for the last ten years of his life had had partial auriculoventricular block, and for the last three and a half years, cardiac failure. He also had several other episodes, some of which may have been embolic. That much of the story is fairly certain, but from then on to discuss the etiology is simply conjecture.

One diagnosis that might fit most of the findings is that of hypertensive and coronary heart disease.

Involvement of the coronary arteries could well explain the long duration of auriculoventricular block, which is not exceptional. The electrocardiogram is entirely in keeping with a diagnosis of coronary heart disease. It is also possible that at some time in his career the patient had had myocardial infarction, although we have no specific evidence either clinically or by electrocardiogram to support this diagnosis. One thing that made me consider that possibility was the large size of the heart. It seemed just a little too large to be explained by hypertension of mild degree, even though it had lasted for ten years. Another point that made me consider the diagnosis of myocardial infarction was the fact that he had had several episodes, more particularly the last one, suggesting embolism. An embolus could have gone to the brain from the heart wall and produced the terminal neurologic changes. Of course the embolus, if he had one, might have come from the auricle. As in every cardiac death, the question of pulmonary embolus must be considered. I cannot rule it out, although I think it is unlikely. Whether or not he had a slight degree of chronic cor pulmonale on the basis of an old embolus also cannot be decided on the evidence presented. It is possible that he had an arterial embolus at the time of his first really severe illness, when he developed pain in the legs. Where that came from is another matter for conjecture.

What else could fit in with a picture like this? In these conferences a time always comes, after the likeliest diagnosis has been considered, when one should consider unusual diagnoses. Accordingly, in this case, I think that we should at least consider a cardiac tumor. It is well known that primary cardiac tumors may produce prolongation of the PR interval, either from interference with the arterial supply or by direct pressure over a long period of time. By direct invasion of the myocardium they may also produce cardiac enlargement and congestive failure. Cardiac tumors that grow on the endocardial surface may give rise to emboli when portions of the tumor break off. It is usually not possible to make a diagnosis of tumor, especially primary tumor, unless one has been fortunate enough to note the syndrome that is caused by the tumor's projecting into the cavity of the left auricle and causing paroxysmal obstruction of the mitral orifice. In such cases patients have a characteristic dyspnea, which is present while the patient is in the upright position and disappears when the horizontal position is assumed. I do not believe, however, that the diagnosis of tumor should be seriously considered here.

The rare forms of heart disease, such as beriberi and periarthritis nodosa, do not fit too well into this long, chronic course. So I shall stick to my first diagnosis: hypertensive and coronary heart disease.

with cardiac enlargement, congestive failure and partial auriculoventricular block and possibly thrombophlebitis and pulmonary embolism, as well as cerebral embolism.

DR. PAUL D. WHITE: I saw this man several years before he died, and although I had heard from him in the meantime, I did not see him again until a few weeks before he died. I had not the faintest idea why he had auriculoventricular block. At first, the late Dr. Breed, whose patient he was, and I thought that he probably had coronary heart disease. He also had, however, a little hypertension, and I did not know how much of a role that might have played. He continued to have a slight to moderate amount of hypertension throughout the last ten years of life, and during the latter part of his life, especially the last three weeks, he had intractable congestive failure. Undoubtedly the earlier gallop rhythm, as Dr. Williams said, was due to auriculoventricular block and that is what we ascribed it to, undoubtedly presystolic at that time. Later the patient had a clear-cut pulsus alternans and extra sounds but no murmurs; we then ascribed the fourth sound early in diastole to dilatation of the heart, which was justified because he had both types of gallop rhythm. My final diagnosis agreed with that of Dr. Breed — coronary and hypertensive heart disease, with intractable failure. I thought that the cerebral vascular accidents were embolic rather than hemorrhagic.

DR. CHESTER M. JONES: Is there anything in the x-ray films of the chest that suggests pulmonary embolism?

DR. LAURENCE L. ROBBINS: Not unless what was said to have been pneumonia could have been an infarct. The films are not particularly good, and there is no follow-up to tell how the pneumonia cleared.

CLINICAL DIAGNOSES

Coronary and hypertensive heart disease.
Congestive heart failure.
Cerebral embolism.

DR. WILLIAMS'S DIAGNOSES

Hypertensive and coronary heart disease.
Congestive heart failure.
Thrombophlebitis and pulmonary embolism?
Cerebral embolism?

ANATOMICAL DIAGNOSES

Idiopathic cardiac hypertrophy: left ventricle.
Mural thrombi: left ventricle and right auricle.
Pulmonary infarction of right upper and left lower lobes.
Chronic passive congestion of liver and spleen.
Central necrosis of liver.
Right hydrothorax, slight.
Cerebral infarction, bilateral, old and recent.

PATHOLOGICAL DISCUSSION

DR. BENJAMIN CASTLEMAN: I can tell you what we found, but I am not sure that I can name the disease this man had.

In the interstices of the trabeculae carneae of the left ventricle were thrombi that were only slightly adherent to the heart muscle itself; they could easily be picked off but had definitely occurred ante mortem (Fig. 2). The heart was enlarged, weighing 550 gm., and there was hypertrophy of the left side consistent with a moderate degree of hypertension. The coronaries, however, looked quite good. There were a few slightly atheromatous plaques but no appreciable narrowing. I am fairly certain that coronary disease itself played no part in the symptoms.

DR. WHITE: Might it be possible that the small vessels supplying the auriculoventricular junctional tissues were affected?

DR. CASTLEMAN: I doubt it because the myocardium underneath these thrombi showed no evidence of old or recent infarction. There were a few small areas of fibrosis in a few sections of the myocardium throughout the heart, but we were unable to find anything that we could call an infarct, and there was no cellular infiltration, which probably rules out Fiedler's myocarditis.¹

DR. WHITE: The fibrosis I suppose was of other origin than coronary.

DR. CASTLEMAN: Yes. There was no intimal fibrosis such as one sees with a vitamin deficiency, although in these cases one often finds mural thrombi in the left ventricle wall such as were found here.

DR. WHITE: The prolongation of the PR interval might have been rheumatic in origin. Was there any evidence of that?

DR. CASTLEMAN: No.

A PHYSICIAN: Is it not unusual to have a PR interval of 0.3 second with rheumatic fever?

DR. WHITE: It is rare, but it does occur.

DR. CASTLEMAN: In the brain there was an old linear infarct in the right temporoparietal region.

The recent episode was a hemorrhagic infarct on the left parietal region, undoubtedly due to an embolus from the left ventricle.

DR. WHITE: Every year we have at least one case of heart disease of unexplained origin. I suppose that this is the one for this year.

DR. WILLIAMS: How about the duration?

DR. CASTLEMAN: That is against it. I believe that in the longest case of Fiedler's myocarditis the patient survived only eighteen months. Also, this man was well nourished and showed no evidence of a vitamin deficiency.

FIGURE 2.

DR. CASTLEMAN: No; several months ago we had one that was similar to this — a patient with emboli to the mesenteric vessels from cardiac mural thrombi.²

DR. WHITE: It hardly seems as if hypertension alone could have explained the clinical picture.

DR. CASTLEMAN: The gross appearance of the heart fits with Fiedler's myocarditis or beriberi heart.

Mural thrombi were also present in the right auricle, and there were pulmonary infarcts in the right upper and left lower lobes.

CASE 30392

PRESENTATION OF CASE

A nineteen-year-old farmer was admitted to the hospital for study.

The patient had had pertussis, chicken pox and scarlet fever as a child but had otherwise been in good health until five months before admission, when he developed a severe sore throat and swollen

lymph nodes in the neck. He felt quite ill and remained in bed. He was said to have been treated heavily with sulfonamides, of which he apparently received "three bottles" over a period of two or three weeks. The course of the sore throat was apparently not altered by the medication, and "the tonsils sloughed out." Either immediately after the drug was stopped or three to five days later, he suddenly developed itching all over the body, with

swelling of the neck and ankles and a blister on the wrist. No more sulfonamide was given. The swelling subsided in three days, and he slowly recovered in the following two or three months. He was able to work on the farm but he noted progressively increasing generalized fatigue. During the entire period he was under the observation of his family physician, who informed his mother that from time to time the patient had some albumin in the urine. There was no definite statement as to when albuminuria was first noted, and the amount was said to be "not alarming." He had received some liver and iron and had been told by his physician that he was improving and that his blood pressure was falling. Three weeks before admission, because of generalized aches, he went to bed, where he remained. One week later he developed bleeding and soreness about the base of the glans penis, and four days before entry he began to have tenesmus and bloody oozing from the rectum. There was one episode of vomiting the day before admission. He had lost a total of 20 pounds. There was no gross hematuria, increased frequency, nocturia or dysuria.

Physical examination showed a well-developed, slightly pale, chronically ill young man who was too weak to sit up. There were occasional questionable petechial lesions on the outer aspect of the left thigh. A large exudate was seen in the left fundus; the vessels were thin and there were no hemorrhages. The tongue was dry and coated. The breath was slightly uriferous. The pharynx was moderately injected. The tonsils were small. The left border of cardiac dullness was felt 8.5 cm. from the midline. The sounds were of good quality and regular. Grade 1 apical and pulmonic systolic murmurs were heard. The lungs were clear. The abdomen was normal. There was partial hypospadias involving the glans; and a bleeding ulcer under the foreskin behind the glans. There were a few small hemorrhoids. A coarse tremor was brought out by exercise, and there was a rare spontaneous muscle twitch. The Chvostek and perineal reflexes were negative. The tendon reflexes were feeble, with a tendency to reduplication. The plantar reflexes were diminished. The sensorium was intact.

The blood pressure was 120 systolic, 75 diastolic. The temperature was 99.2°F., the pulse 86, and the respirations 20.

Examination of the blood showed a red-cell count of 2,530,000, with 8 gm. of hemoglobin. The white-cell count was 7400, with 87 per cent neutrophils. A blood Hinton test was negative. The urine was cloudy, with a pH of 5.5, a specific gravity of 1.010 and a +++ test for albumin; the sediment contained 4 to 5 white cells, 15 to 20 red cells and rare granular and red-cell casts per high-power field and many triple phosphate crystals. The stools were guaiac positive.

A roentgenogram of the chest was negative.

The blood nonprotein nitrogen was 100 mg. per 100 cc. The carbon dioxide combining power was 19.5 millimols per liter, and the chloride 90.9 milliequiv. The uric acid was 14 mg. per 100 cc., and the blood protein 8.4 gm., with an albumin of 4.0 gm. and a globulin of 4.4 gm., an albumin-globulin ratio of 0.9. The calcium was 11.4 mg. per 100 cc., the phosphorus 22.2 mg., and the phosphatase 4 Bodansky units. The last three determinations were done on hemolyzed blood, and a repeat test for phosphorus gave a level of 16.0 mg. per 100 cc. The phenolsulfonephthalein excretion was less than 5 per cent at the end of two hours.

The patient received daily intravenous fluids, including sodium lactate. His condition steadily became worse. On the third day the nonprotein nitrogen was 128 mg. per 100 cc. For the first three days the urinary outputs were 1000, 1500 and 2000 on an intake of 1250, 2000 and 3700 cc., respectively. The character of the urine remained the same except that the pH rose to 7.5. The blood pressure was 140 systolic, 80 diastolic. On the sixth day he became semicomatose and had frequent muscle twitches. Ulcers developed in his mouth and extended into the pharynx. There were edema and swelling of the perioral tissue. The stools gave a +++ test for guaiac, and there was a discharge of serosanguineous fluid from the oral cavity. His pulse rose to 120. The lungs, however, remained clear and the heart sounds were of good quality. The following day the urinary output fell to 500 cc. on an intake of 4500 cc. On the afternoon of that day the blood pressure fell to 110 systolic, 30 diastolic, and the pulse was 100; the patient died shortly thereafter.

DIFFERENTIAL DIAGNOSIS

DR. WILLIAM BECKMAN: All the information in the record adds up to the fact that this man died of renal failure. From the history we learn that he had had albumin in his urine and that his blood pressure must have been elevated since his physician said it was falling. The bleeding tendency, the weight loss and the aching are also consistent with uremia.

The physical examination also provides evidence for the diagnosis of renal failure. The retinal exudate and the tremor are frequent findings, and petechial lesions are occasionally seen in uremia. Of course in the terminal stage of the disease one would have liked to note a higher blood pressure, but the normal values discovered in the hospital are certainly not incompatible with the condition.

The laboratory data confirm the impression of renal failure. Anemia is an almost constant feature, as are albuminuria and the finding of red cells and casts in the sediment. The elevated nonprotein nitrogen, the acidosis, — as evidenced by the diminished carbon dioxide combining power, — the

elevated uric acid and the marked increase in phosphorus concentration, all point toward markedly diminished renal function. I believe that with this array of evidence no other diagnosis can be supported.

Other causes of an elevated nonprotein nitrogen, such as dehydration and severe diarrhea, would not exhibit all the findings in the history and physical examination, and of course he did not have diarrhea.

Having now made out a case for renal failure, the important part of this exercise is to try to decide on the etiology of the kidney disease that was present. Of course any form of renal disease, from glomerulonephritis to amyloidosis, can lead to uremia, and it is usually difficult to tell precisely which one is present in any given case. It seems possible to rule out amyloidosis because there was no evidence of any condition, such as chronic suppuration, rheumatoid arthritis or tuberculosis, that is commonly associated with amyloidosis. Likewise one can rule out chronic pyelonephritis, since there was no evidence of an infection of the urinary tract; at least there is no report of a positive urine culture.

My first suggestion is that the streptococcal infection that he suffered five months prior to admission gave rise to an acute glomerulonephritis that remained active until death. I have no way of ruling out this possibility, but I should not expect acute nephritis to subside for a brief period and then flare up again. From the record one cannot be absolutely certain that there was a remission with a relapse, since his physician apparently found an elevated blood pressure during the period when he was well and able to work.

A second possibility is that following the scarlet fever that he had as a child he developed an acute glomerulonephritis, which had been smoldering in a latent state up to the time of the infection that precipitated the present illness. The latter infection may have exacerbated the already present nephritis and produced this picture of chronic renal failure.

A third possibility is that this patient's renal disease was the result of a reaction to the sulfonamides that he was given in fairly large quantities. A sulfonamide reaction is the only interpretation that I can think of for the attack of itching of the skin and swelling of the ankles. It has been amply demonstrated in the past few years that the sulfonamides are capable of producing renal disease, which is, I believe, of a somewhat variable nature. Rich* has reported some cases in which the patients developed periarteritis nodosa, presumably as a result of the hypersensitivity to the sulfonamide. The fact that this man had such marked muscular aching might be explained on the basis of periarteritis nodosa. Also, the petechial rash is more consistent with this diagnosis than it is with plain uremia.

Finally, it is possible that a latent nephritis, which occurred at the time of the scarlet fever, could be exacerbated not only by the streptococcal infection but also by the sulfonamide reaction.

I have no way of differentiating the last four possibilities that I have mentioned. However, making use of the meager clinical data that I have, I shall commit myself to a diagnosis of sulfonamide reaction with resultant periarteritis nodosa.

CLINICAL DIAGNOSIS

Chronic glomerulonephritis.

DR. BECKMAN'S DIAGNOSIS

Sulfonamide nephropathy, with resultant periarteritis nodosa and renal failure.

ANATOMICAL DIAGNOSES

Chronic glomerulonephritis, with superimposed acute pyelonephritis.

Sulfonamide nephropathy?

Balanoposthitis, acute and chronic.

Cystitis.

Parathyroid hyperplasia, secondary.

Bronchopneumonia.

Petechial hemorrhages of lungs, stomach and esophagus.

PATHOLOGICAL DISCUSSION

DR. BENJAMIN CASTLEMAN: The autopsy on this boy showed a small pair of kidneys, weighing 100 gm., thus indicating that the renal disease dated back for a long period of time — certainly longer than five months. Microscopic examination showed marked dilatation of the tubules, which is the best anatomic evidence that we have of renal impairment of any type. The changes in the glomerular tufts were characteristic of chronic glomerulonephritis, with numerous capsular adhesions. In addition there was a fair amount of lymphocytic and polymorphonuclear infiltration and fibrosis of the stroma.

How much the sulfonamides had to do with this uremic death is difficult to answer. There is no doubt that he received sulfonamides after his kidneys had contracted, and the drug must have been an added burden to the kidneys, which might have precipitated the acute renal failure. We have no definite evidence in the kidneys, however, that this was the case, and the findings are consistent with a chronic glomerulonephritis and a superimposed acute infection. The patient did have a mild cystitis, and further evidence that he had had renal disease for a long time was a moderate degree of secondary hyperplasia of all four parathyroid glands.

The heart was slightly enlarged and weighed 330 gm.

COMPENSATION FOR EMERGENCY CARE IN CASES OF INDUSTRIAL INJURY

THIS issue of the *Journal* carries a communication from the Secretary that deserves the notice of all the members of the Massachusetts Medical Society, particularly those who occupy regular positions on a hospital staff. Heretofore the right of staff physicians to compensation for services rendered those injured in industry has been challenged by many insurance companies. Their refusal to pay for such services was based on certain decisions of the Massachusetts Supreme Court. These decisions seem to have arisen out of the Court's interpretation of the law as it relates to hospitals and to the principle of free choice of physician as provided for in the Massachusetts Workmen's Compensation Act.

The layman reading these decisions is led to believe that the Court regards hospitals as merely asylums for the poor. Although it is true that the law frequently lags a bit behind what has come to be regarded by the people as established social practice, it seems incredible that it should lag so far behind as not to recognize what everybody, for a long time, has come to accept as the hospital's function in the scheme of American life. The present-day hospital serves the whole community without any loss of emphasis on its original purpose. It has done this as the result of public demand, in keeping with scientific progress and a changing way of life.

The Workmen's Compensation Act was established for the purpose of protecting the workman and his family from the hazards of industry. When the workman ran afoul of these hazards, the responsibility for his care was placed by law on industry itself, as a legitimate addition to the costs of production. It is little wonder, then, that many physicians are bewildered by these decisions of the Court, which put doctors in the position of sharing costs that are imposed elsewhere by the law. Mrs. Tousant, the able chairman of the Massachusetts Industrial Accident Board, has expressed, in conference with the Committee on Public Relations of the Society, the Board's dissatisfaction with the way in which many industrial injuries have been handled. She is agreed that the confusion caused by the issues discussed here may be partly responsible.

The agreement reported elsewhere in this issue is the result of many conferences held by the Massachusetts Industrial Accident Board with the Medical Advisory Committee of the Board, a subcommittee of the National Council of Claims Executives on Compensation Insurance and a subcommittee of the Committee on Public Relations of the Massachusetts Medical Society. Drs. Daniel J. Ellison, David D. Scannell and Gordon M. Morrison, who comprise the latter subcommittee, deserve the sincere thanks of the Society.

This agreement has done much to clear the air, and it is the obligation of every hospital-staff physician to see to it that the confidence of the Industrial Accident Board has not been misplaced.

SHORTAGE OF NURSES STILL ACUTE

FOLLOWING a summer in which the war news became increasingly good, the needs of the military services for nurses have grown steadily more acute. The victories that are winning the war are taking their toll, on every front, in casualties. All the nurses actively taking part in the combat areas abroad and in the military hospitals at home and many of those in other types of foreign service are reaching the point where they themselves need relief. With the present plan for releasing those who cannot continue under the strain and for giving leave to those who have had long stretches of service, the need for additional enlistments continues.

According to official reports, the New England states were 120 short of meeting their quota of 1023 for the first half of the year, although both Massachusetts and Rhode Island went well over their state quotas. They are now asked to provide 1000 more nurses during the last part of 1944, at least half of them by November 1. The Massachusetts quota — 526 — is naturally the largest.

Most of these enlistments must come from new and recent graduates. It is expected that at least 30 per cent of the new graduates from the schools of nursing will be available for military service, 50 per cent for essential civilian service, and perhaps 15 per cent — those specially qualified — for post-graduate study. No recent graduate will be fulfilling her professional obligation at this critical time if she enters private-duty nursing or office nursing, both of which must be cut to the minimum until the acute shortage is relieved.

Although some institutions and agencies seem to have weathered their worst periods of shortage, others find things more and more difficult with each passing month. This is particularly true of some of the hospitals without schools of nursing, which are in extreme need of head nurses, supervisors and nurses for the general staff. If, as now seems apparent, the general military hospitals, such as the Cushing, the Lovell and the Edwards, here in Massachusetts are also going to need civilian nurses for the next few months to supplement the staff of Army nurses, then there is no likelihood

that the efforts to see that nursing service is equitably distributed to meet the most essential need can be relaxed.

It is important for every physician to know the situation and to use his influence to restrict the use of nurses in private cases or noncritical office work until the needs of the armed forces and civilian hospitals are adequately met.

MASSACHUSETTS MEDICAL SOCIETY SECRETARY'S OFFICE

It seems important that those of our members who occupy staff positions in Massachusetts hospitals should have called to their attention in this special manner an agreement that has just been concluded through the aegis of a subcommittee of the Massachusetts Medical Society appointed to confer with the Medical Advisory Committee of the Industrial Accident Board. The subject on which this agreement has been reached has been a source of contention over the years. The elimination of this contention should pave the way for better care of those injured in industry and for a better understanding between all concerned.

The report of Drs. Daniel J. Ellison, David D. Scannell and Gordon M. Morrison, which ably and clearly set forth this agreement and the manner in which it may be maintained, is as follows:

This report is a follow-up in a matter on which a preliminary report was made one year ago.

This committee was appointed at the request of the Industrial Accident Board to recommend procedures whereby the medical care and surgical care of the injured workman might be improved. It was and still is the opinion of this committee that the surgical staffs of recognized hospitals, by and large, represent the men in any given community most able to cope with surgical conditions.

Our first procedure was to attempt to make these men more willing to care for or handle industrial accident cases while they were on duty on ward service. To this end, through the co-operation of the chairman of the Industrial Accident Board, it has now been agreed by all the insurance companies handling this type of business that the man rendering emergency treatment to an injured workman shall be paid for such treatment. In defining first-aid treatment it may be said that emergency treatment ranges from simple first-aid to an extensive operation for the relief of a compound fracture. Reasonable charges submitted by any registered physician in this state will be honored. There shall be no change in the relation between the patient and the hospital-staff physician as it now exists in the various hospitals of the Commonwealth. The problem of the surgeon on duty caring for an injured employee in the ward without being paid except for the emergency treatment cannot be solved by any method except the passage of an amendment to the law by the General Court providing for the payment for such services or a reversal of the ruling previously made by the Supreme Court. It is the opinion of the committee that, whereas surgeons on ward service render equally as able care to both ward and private patients, it might be well to institute proceedings that would change this rather unfortunate state of affairs.

Payment will not be made for services rendered by interns or residents but for work actually done by surgeons

recognized by a hospital, whether or not on duty. This we believe to be a step forward in the better care of the injured workman.

It is also agreed that the injured employee, if conscious, shall be offered two lists of physicians, — one a list of staff doctors selected by the insurer and the other a complete list of the members of the hospital staff, including the courtesy staff, — with the understanding that the employee has a free choice of any doctor on either of these lists. On the other hand, should the injured employee choose as his physician a doctor connected with some hospital other than the one to which he has been taken he may be removed without prejudice to that hospital, where the physician of his choice may care for him.

Your committee believes that it is impossible to prevent a certain number of these patients being taken to unaccepted hospitals and being cared for by men of limited ability, but that the solution of this part of the problem lies in an educational program designed to teach people the difference between recognized and unrecognized hospitals. The problem is not so simple as it seems at this time owing to the absence of many of the best men in the service and to the fact that their places have been taken by men of considerably less maturity in judgment.

There is one other arrangement that has recently been concluded that in some cases may obviate this difficulty. Through an agreement with the Blue Cross, an injured employee insured under the Blue Cross may be transferred from a ward to a semiprivate or private room and the difference in expense will be paid by the Blue Cross, making such an employee the private patient of the surgeon on duty or of the surgeon chosen by the employee.

It is further thought that freedom of choice of physician by the injured employee should at no time be interfered with.

It is the desire of the chairman of the State Industrial Accident Board that a committee of this type be continued.

This agreement should be studied carefully, and every assistance should be given to Massachusetts hospitals by their respective staff members in putting its provisions into practice.

The Industrial Accident Board has already addressed the hospitals in this same vein.

MICHAEL A. TIGHE, *Secretary*

DEATHS

FAULKNER — Herbert K. Faulkner, M.D., of Keene, New Hampshire, died September 15. He was in his eighty-sixth year.

Dr. Faulkner received his degree from Harvard Medical School in 1885 and practiced in Keene for forty years before retiring in 1920.

Five daughters and two sons, one of whom is Captain James M. Faulkner (MC), U.S.N.R., survive.

OUTHOUSE — John S. Outhouse, M.D., of Shelburne Falls, died June 20. He was in his seventieth year.

Dr. Outhouse received his medical degree from McGill University, Montreal, in 1898.

His widow, one daughter and two grandchildren survive.

SHERMAN — Frank M. Sherman, M.D., of West Newton, died September 14. He was in his eighty-eighth year.

Dr. Sherman received his degree from Harvard Medical School in 1881. He had retired several years ago.

His widow, two sons and a daughter survive.

WAR ACTIVITIES

INDUSTRIAL HYGIENE

A HEALTH PROGRAM FOR SMALL INDUSTRIES

A campaign for the advancement of industrial health in the small industries of the Detroit area is being sponsored by the Wayne County Medical Society. The main objective is to provide emergency care in these plants and eventually to convince the management that a health program is not costly but economically profitable, even though it necessitates an initial expenditure for first-aid stations and certain equipment.

When a sufficient number of doctors have notified the society of their availability to assist in the program, letters will be sent by the medical society to industries in the area employing 25 to 1000 workers that do not employ a full-time plant physician. The City of Detroit Department of Health has offered to render service or advice regarding occupational diseases found in these plants.

The plan proposes meetings at regular intervals, in each plant, of the president or plant manager, the plant doctor or his appointed representative, the plant or visiting nurse, the first-aid man, the director of the safety committee, a representative of the employees and the personnel or employment manager. Suggested topics for these meetings include: disabilities from accidents; first-aid at the plant; physical examination and health of the worker; noncompensable illnesses such as colds, other infections and surgical disabilities; co-operation of the family physician in cutting down loss of workdays; ventilation and sanitary conditions in the plant; nutrition of the workers and food conditions; and contagious diseases and co-operation with the public-health department. — Reprinted from *Industrial Hygiene News Letter* (August, 1944).

CORRESPONDENCE

CASH BENEFITS

To the Editor: The editorial "Massachusetts EMIC Program" in the September 7 issue of the *Journal* was interesting and timely. It called to mind an editorial appearing in the January 20, 1938, issue of the *Journal*, entitled "Group Health Association, Incorporated." That editorial questioned the wisdom of the American Medical Association's opposition to Group Health Association, Washington, D. C., and suggested that the manner in which the medical profession reacted to medical-service plans was of vital importance to physicians. The subsequent decision of the Supreme Court of the United States concerning the opposition of the American Medical Association and the unfortunate publicity that accrued to the medical profession seem to have amply supported the former editorial comment.

In the present instance the American Medical Association has again taken action that may be detrimental to physicians. It has recommended that the cash allotment method of dis-

bursing funds under the EMIC program be substituted for the present method of directly paying physicians for the services they render. The advocacy of such cash benefits by the profession may lead the public to believe that physicians approve the expenditure of the public's money under the pretext of medical care without concern whether or not that money is actually spent on medical care. The public may also infer that the profession is not concerned about the quality of medical care purchased with government funds. Finally, the public may conclude that doctors wish to be in a position to negotiate with each of these mothers the fees that they should pay and thus disregard the decision of Congress to free such mothers from the worries of medical expense.

If the public should feel that doctors are more concerned with protecting the present system of medical practice than in economically distributing the cost of medical care and improving its quality, then the public is likely to pay little attention to the advice of the profession in the consideration of programs for the improvement of medical care. Thus it would seem that the advocacy of cash benefits by the official bodies of the medical profession is a matter of importance to physicians, for they suddenly may find that their official representatives have once again subjected the medical profession to public criticism.

BOOK REVIEWS

Psychiatry in War. By Emilio Mira, M.D. 8°, cloth, 206 pp., with 6 figures. New York: W. W. Norton & Company, Inc., 1943. \$2.75.

Mira, a former professor of psychiatry in Barcelona, served during the Spanish Civil War as an active physician in the treatment of mental diseases in the Republican Army. His account is by far the best that has been written on psychiatry during this war and is of outstanding value because of its clear picture of the effects of war on the mind of man. The book forms a fitting introduction to the treatment of the many neuropsychiatric problems that are appearing in World War II, and this timely contribution will be welcomed by all physicians who have to do with the care of the American soldier mentally disturbed by war conditions. There are excellent chapters on the effect of bombing on the civilian population, in addition to the case histories and personal experience of the author at the front. The morale of an army under stress is given particular consideration.

The author is well known in this country, having delivered addresses here in 1933 and more recently being the Salmon Lecturer at the Academy of Medicine, New York City. The book comprises the latter lectures, plus additional material, particularly on the diagnostic apparatus devised by the author for estimating the fitness of a person to serve in the Army. This apparatus, which Mira believes is an efficient means of military selection, is now being used for investigation in this country.

The book is an important landmark in military psychiatry for it contains material not found elsewhere. It is well written and factual, and the conclusions should have a wide field of application both in military and in civilian life.

The Conquest of Epidemic Disease: A chapter in the history of ideas. By Charles-Edward A. Winslow, Dr.P.H. 8°, cloth, 411 pp. Princeton, New Jersey: Princeton University Press, 1943. \$4.50.

This volume may well be considered a classic. It approaches the problem of the history of the attack on epidemic diseases with a point of view that differs from other writings. In part it is medical history; in part an anthology of the writings of the makers of that history; and in part the clear thinking of C.-E. A. Winslow. The author has attempted to depict how the leaders of medical science visualized their problems. So far as possible he has told their story in their own words, and has so woven them into the text that at times, without quotation marks, it is difficult to separate the original writer from his historian. The field of epidemic disease is unfolded from the days of the Old Testament

down through the ages to Charles Value Chapin, Francis Torius, Rush, Panum, Budd, Snow, Pasteur, Koch and many others are reviewed by their thoughts rather than by their acts.

Winslow calls his work "a chapter in the history of ideas." It seems more than that. The ideas of the masters are integrated and interpreted by a master. This volume is not a textbook and may not be suited to the library of the entire medical profession but it will be a delight to those interested in medical history, to those trying to learn more regarding human understanding, to the busy doctor desirous of spending a quiet evening before the fireside and to a limited number of public-health workers, both medical and nonmedical.

The Genealogy of Gynaecology. By James V. Ricci, MD 4°, cloth, 578 pp., with 53 illustrations. Philadelphia: The Blakiston Company, 1943. \$8.50.

This is an authoritative, scholarly and well-documented history of gynecology from its remotest archaic beginnings through the Assyrian, Babylonian, Egyptian and Hindu epochs, the classic Graeco-Roman age, the Talmudic, Byzantine and Arabic eras and the Middle Ages and Renaissance to the end of the eighteenth century. From all these epochs there is an abundant bibliography and the reproduction of fifty-three well-selected illustrations, chiefly of gynecologic instruments and of developing anatomical concepts. In his preface, as in his gracious dedication to the Harvard Medical School, the author freely acknowledges his indebtedness to previous writers but modestly underestimates the wide ranging and painstaking research that the accumulation of his material must have required. His work is a priceless gift to the profession, and one waits with eager anticipation for the subsequent volume, promised in the introduction by Dr. Schumann, of Philadelphia, covering the period of the nineteenth century.

Reaction to Injury: Pathology for students of disease based on the functional and morphological responses of tissues to injurious agents. By Wiley D. Forbus, M.D. 4°, cloth, 791 pp., with 532 illustrations, 20 of which are in color. Baltimore: Williams & Wilkins Company, 1943. \$9.00.

Forbus's new textbook of pathology follows the arrangement that has been made familiar by MacCallum's book—an etiologic compilation based on the type of injury causing disease. The present volume contains introductory material, a brief chapter on the history of pathology, a classification of the causes of disease and a full discussion of infectious diseases. The author states that a second volume covering the other fields of pathology is in preparation but that the importance of infectious diseases in wartime makes the publication of the first volume worth while at the present moment.

The discussion of the topics within the scope set for the work as it now stands is more complete than in most pathology texts, such as those of Boyd and Karsner. The presentation of material is clear and critical; both sides of controversial questions are given, and dogmatic statements are meticulously avoided. The pathology of the various infectious diseases is set in relation to the picture of the diseases as wholes, and an adequate basis for the difficult transition from preclinical to clinical studies is provided. This has been accomplished to a certain extent at the sacrifice of considerations of disease as a biologic phenomenon, particularly in its relation to biochemistry.

There are many advantages in the arrangement of a text according to the type of injury causing disease. These accrue chiefly from the fact that etiology receives the emphasis that it deserves, yet it often separates by hundreds of pages subjects that should be considered together. For instance, Forbus discusses glomerulonephritis among the acute and chronic, nonsuppurative inflammatory processes, whereas vascular diseases of the kidneys will be considered in the volume that has not yet appeared. "You pay your money and take your choice."

The illustrations are definitely superior to those of most texts of pathology now in general use. The photographs of gross specimens are excellent, as are most of the photomicrographs. Some of the latter could be improved by procuring better fixed and stained preparations (for example, Figs. 309,

345 and 508). The colored plates are made from Kodachromes of varying merit.

References follow each chapter. These are well chosen from the student's viewpoint but are considerably out of date, few of them being more recent than four years before publication of the volume. In some instances, later material is included in the text than in the bibliography.

Within the fields covered by this volume, the text is one of the best now available. It will appeal to the better students, which is as it should be, and to those clinicians and pathologists who wish a reference work on the pathology of infectious diseases. Forbus's book is a welcome change from the numerous textbooks of pathology that are little more than catalogues of disease. Without supplementation by another text, it lacks too many important topics (for example, arteriosclerosis and tumors) to make it suitable for a second-year course in pathology as it stands.

BOOKS RECEIVED

The receipt of the following books is acknowledged, and this listing must be regarded as a sufficient return or the courtesy of the sender. Books that appear to be of particular interest will be reviewed as space permits. Additional information in regard to all listed books will be gladly furnished on request.

Office Treatment of the Nose, Throat and Ear. By Abraham R. Hollender, M.D., associate professor of laryngology, rhinology and otology, University of Illinois College of Medicine, and otolaryngologist, Research and Educational Hospitals, Chicago. 8° cloth, 480 pp., with 33 illustrations. Chicago: The Year Book Publishers, Incorporated, 1943. \$5.00.

This manual is written for the purpose of furnishing details of office treatment not usually found in prescribed college curriculums or in the training provided for residents in hospitals. The work is divided into two sections: the first discusses the general therapeutic methods used in all diseases of the upper respiratory tract, and the second considers the various diseases of the nose, sinuses, mouth, larynx and ear.

The Religious and Philosophical Aspects of van Helmont's Science and Medicine. By Walter Pagel. 4°, paper, 44 pp. Baltimore: The Johns Hopkins Press, 1944. \$1.00.

In this monograph an attempt is made to define the position of van Helmont in the history of philosophy.

Safe Convey: The expectant mother's handbook. By William J. Carrington, M.D., attending gynecologist, Atlantic City Hospital, Atlantic County Hospital for Nervous and Mental Diseases, Pine Rest Hospital, Atlantic City Municipal Hospital and Atlantic Shores Hospital. 8°, cloth, 256 pp. Philadelphia: J. B. Lippincott Company, 1944. \$2.50.

This manual of personal hygiene for the expectant mother has been written by an obstetrician of large experience. One third of the volume is devoted to the care of the newborn infant. The foreword comprises a short history of obstetric books for the laity.

Minor Surgery. By Frederick Christopher, M.D., associate professor of surgery, Northwestern University Medical School, Chicago, and chief surgeon, Evanston (Illinois) Hospital. Fifth edition. 8°, cloth, 1006 pp., with 575 illustrations. Philadelphia and London: W. B. Saunders Company, 1944. \$10.00.

The text of this edition has been thoroughly revised; many sections have been entirely rewritten, and many new sections have been added. The subjects of wound healing and treatment have been rewritten with particular attention to the local use of sulfonamides, and the administration of penicillin is discussed. The employment of plastic casts in wound treatment is considered. The section on burns has been extensively revised and includes consideration of the use of nonadherent pressure dressings and of plasma administration. A new chapter on preoperative and postoperative care has been added. This includes the following topics: shock and its treatment with blood plasma and other agents; dehydration; hypoprothrombinemia; vitamin deficiency (including vitamin K); preoperative preparation in special

cases; water balance; electrolyte requirements; protein requirements and treatment of hypoproteinemia with amino acids; the use of the Miller-Abbott tube; postoperative pulmonary complications; prophylaxis and treatment of postoperative thrombosis and embolism (including the use of heparin and dicumarol); and postoperative urinary complications (including the use of sodium lactate to increase the pH of the urine during administration).

New subjects considered or emphasized for the first time are tetanus toxoid, new developments in the treatment of varicose veins, ligation of the femoral vein in thrombophlebitis, treatment of pilonidal sinuses, wire sutures in tenorrhaphy, the hanging cast in fractures of the humerus, x-ray treatment for sprained ankles, "paratrooper fracture," walking casts, sternal infusions, treatment of cardiac arrest and employment of intravenous anesthesia.

This authoritative treatise, first published in 1929, should prove of great value at the present time to physicians who are called on to treat minor surgical conditions.

The Hippocratic Oath: Text, translation and interpretation. By Ludwig Edelstein. A supplement to the *Bulletin of the History of Medicine*. 4°, paper, 64 pp. Baltimore: The Johns Hopkins Press, 1943. \$1.25.

The text of the oath is given in both Greek and English. In his interpretation Dr. Edelstein has scrutinized the text, sentence by sentence, and has made extensive use of the writings of ancient authors in his inquiries. The covenant, which precedes the code, and the ethical code are considered separately. The two final chapters discuss the unity of the document and the date and purpose of the oath. This scholarly presentation should be on the shelves of every library.

Health for the Having: A handbook for physical fitness. By William R. P. Emerson, M.D., medical consultant in physical fitness, Aetna Life Insurance Company. 12°, cloth, 146 pp., with 6 illustrations. New York: The Macmillan Company, 1944. \$1.75.

This small manual has been written for the layman, and much emphasis is placed on body weight and personal hygiene. Correct diet is stressed and valuable tables of calories and weight and height are appended to the text.

Physical Foundation of Radiology. By Otto Glasser, Ph.D., professor of biophysics and head of Department of Biophysics, Cleveland Clinic Foundation, Cleveland; Edith H. Quimby, Sc.D., associate professor of radiology (physics), College of Physicians and Surgeons, Columbia University, New York; Lauriston S. Taylor, Ph.D., chief of X-ray Section, National Bureau of Standards, Washington, D.C.; and J. L. Weatherwax, M.A., Philadelphia General Hospital and Graduate School of Medicine, University of Pennsylvania, Philadelphia. 12°, cloth, 426 pp., with 95 illustrations and 53 tables. New York: Paul B. Hoeber, Incorporated, 1944. \$5.00.

This combined work of four authors is an attempt to provide a teaching text in the field of radiologic physics. The manual has been designedly written in an elementary and nonmathematical character. General bibliographies and special references are appended to each chapter for the purpose of furnishing material to teachers who may desire to supplement the text with other material. Throughout the book the place of radiologic physics as a part of modern physics has been kept in mind. There is a special chapter on therapy records, which is amplified by extensive tables of dosage data for both x-rays and radium. The first chapter, which is historical, contains valuable chronologies from the time of Gilbert in 1600 to Kerst in 1940. These tables make the manual invaluable to all those interested in the history of medicine and physics. The book is well printed with a good type and is of a convenient size to handle.

NOTICES

TUFTS POSTGRADUATE COURSES FOR THE GENERAL PRACTITIONER

The Postgraduate Division of Tufts College Medical School has recently announced a series of courses designed for the busy general practitioner who wishes to bring his knowledge up to date. The work is largely given in the New England

Medical Center (Boston Dispensary, Joseph H. Pratt Diagnostic Hospital, Boston Floating Hospital and Tufts College Medical School). Facilities of other hospitals in and around Boston are also available in several of the courses.

Graduates of approved medical schools are eligible for admission to any of the courses. Graduates of other medical schools may be admitted if considered acceptable. Such applicants should submit evidence that they are members of their state medical societies. Applications for admission and requests for further information should be made to the Chairman, Postgraduate Division, Tufts Medical School, 30 Bennet Street, Boston.

Tuition fees are payable on the opening day of each course. In addition, a \$5.00 registration fee covers all courses taken within a twelve-month period and is due on acceptance for study. The registration fee will be forfeited in cases of withdrawal without notification.

Through the Bingham Associates Fund, fellowships for postgraduate study are available for physicians practicing in Maine who are members of the Maine Medical Association. Application should be made to the Chairman. These fellowships are not available to physicians from other parts of New England; the tuition fees, however, are placed at a level calculated to make the courses available to the great body of physicians in New England.

For a limited number of physicians, room and board are available at the New England Medical Center. Rates for room are \$10.00 double and \$12.00 single per week. Meals are available through the purchase of meal tickets. Reservations for room accommodations *must be made* in advance and should be addressed to Mr. Frank E. Wing, Director, Boston Dispensary, 25 Bennet Street, Boston.

AMERICAN BOARD OF OBSTETRICS AND GYNECOLOGY

A number of changes in regulations and requirements were put into effect at the last annual meeting of the American Board of Obstetrics and Gynecology. These were designed to aid civilians as well as candidates in the service. Among these is the waiver, temporarily, of the requirement of the American Medical Association for men in the Army or Navy, especially for those who proceeded directly or almost so from hospital into military service, on a statement of intention to join promptly on return to civilian practice. At this meeting the Board also decided to accept a period of nine months as an academic year in satisfying the requirement for certain years of training. This is only for the duration and even men who are not eligible for military service but who are nevertheless in hospitals where the accelerated program is in effect have been allowed to submit this short-time period of training in lieu of the previous requirements.

Beginning with the next written examination, which is scheduled to be held on the afternoon of February 3, 1945, the Board will limit the written examination to a maximum period of three hours, and in submitting case records, all obstetric reports that do not include measurements, either by calipers and, as indicated, by acceptable x-ray pelvimetry, will be considered incomplete.

Prospective applicants or candidates in military service are urged to obtain from the office of the Secretary a copy of "Record of Professional Assignments for Prospective Applicants for Certification by Specialty Boards," which will be supplied on request. This record was compiled by the Advisory Board for Medical Specialties and is approved by the offices of the Surgeons-General, having been recommended to the services in a Circular Letter No. 76 from the War Department Army Service Forces, and referred to as the "Medical Officer's Service Record." These will enable prospective applicants and candidates to keep an accurate record of work done while in military service and should be submitted with the candidate's application, so that the Credentials Committee may have this information available in reviewing the application.

Applications and a bulletin of detailed information regarding the Board requirements will be sent on request to the Secretary's Office, 1015 Highland Building, Pittsburgh 6.

Applications must be in the office of the Secretary by November 15, 1944, ninety days in advance of the examination. The time and place of the Spring 1945 (Part II) examination will be announced later.

NEW ENGLAND HOSPITAL FOR WOMEN AND CHILDREN

The monthly clinical conference and meeting of the staff of the New England Hospital for Women and Children will be held on Thursday, October 5, in the classroom of Nurses' Residence at 7:15 p.m. A motion picture on cat anesthesia will be shown. Dr. Mabelle C. Hiscock will be chairman.

THE APPLICATION OF PULMONARY PHYSIOLOGY TO THERAPEUTIC PROCEDURES*

With Special Reference to the Use of Oxygen

CECIL K. DRINKER, M.D.†

BOSTON

DURING many years of experimental work in what I call mammalian or medical physiology, I have been drawn again and again to observations on the lungs and, on looking back, am struck by the diverse lines of inquiry that have been necessary. Physiology, anatomy, pathology, surgery, all have had their place, with emphasis on the fact that neither the experimenter in the laboratory nor the agent of disease can succeed in doing just one thing to the lungs. The functions, structure and functional relations of lung tissue are so vital, so delicately ordered and so immediately of consequence to other parts of the body as to make it necessary to view events in them through a number of fundamental medical disciplines.

Reduced to simplest terms, breathing originates in the respiratory center in the medulla. The metabolism of this collection of nervous tissues continuously produces carbon dioxide. When carbon dioxide reaches a certain concentration in this center, a series of impulses are discharged that result in inspiration. Since carbon dioxide is a substance that diffuses rapidly through a watery medium, it is to be expected that as it accumulates in the center it will also be diffusing out toward the blood. If one breathes a gas mixture containing 5 to 10 per cent carbon dioxide, the blood going through the respiratory center will contain more than the usual amount of the gas and outward diffusion will be slowed, which, in turn, will favor the more rapid attainment of discharge concentrations and a consequent increase in breathing.

One may believe that the discharge concentration for the center is not always the same. It depends on the setting or condition of the center at the moment, somewhat as one might expect to have to apply a hotter poker to a pile of damp

powder to explode it than would be necessary for dry powder. It is this setting of the center that is most important. There are few drugs that stimulate breathing, but there are many that depress it. Ether, alcohol and chloroform all depress breathing when they pass beyond their initial effects. Morphine is notable in this direction, and the barbiturates all produce a certain degree of anoxia in animals breathing air if they are given to the point of producing anesthesia. Far more important than any drug for its dampening effect on the respiratory center is lack of oxygen. By this is meant that essential automatic discharge of impulses by the center as a result of the accumulation of carbon dioxide is progressively hindered as anoxia develops. The increase in breathing following inhalation of 7 per cent carbon dioxide becomes less if it is repeatedly tested during anoxia produced slowly by means of carbon monoxide. It is quite true that in the carotid and aortic bodies chemoreceptors are present that are stimulated by oxygen lack, but the hyperpnea resulting from oxygen lack is a weak affair compared with what is obtained from carbon dioxide in the presence of normally ample oxygen. Furthermore, stimulation of breathing through oxygen lack is in many reactions similar to nerve stimulation. To be effective there must be a sudden rise in the intensity of the stimulus. Anoxia, as one usually sees it, develops insidiously and may become quite marked without noticeably disturbing the rate or volume of the breathing. In summary, so far as anoxia is concerned, the reactions of the central nervous system are not on the whole very serviceable against the progress of the condition. It is curious that evolution has not resulted in better protection by the central nervous system against oxygen lack, but the fact is that anoxia begets anoxia, an axiom too often forgotten in the management of patients.

If oxygen lack is accompanied by a gradual loss of efficiency in the central mechanism controlling breathing and thus by depreciation of the oxygen

intake, its results on the smallest blood vessels are even more significant. It was Krogh's idea that anoxia is responsible for many localized dilations of capillaries. Lewis, a little later, concluded that as a result of anoxia, and of trauma of the most varied sorts, an "H substance" is formed locally and causes the reaction in question. This

FIGURE 1. *Reconstruction of Capillaries in the Walls of Alveoli (x280) (reproduced from Miller by permission of the publisher).*
Note the absence of long capillaries. The total surface area for gas diffusion provided by this close net is estimated at 140 square meters in a normal adult.

idea, supported by a variety of ingenious experiments, induced many people to neglect Krogh's position. He considered lack of oxygen to be a special form of chemical injury, which caused capillary dilatation through formation of a variety of substances, not of a single histaminelike product. This conception is probably more nearly correct than the simpler one of Lewis and puts anoxia in the special position it deserves. I know of no exception to the fact that systemic capillaries in all parts of the body dilate as a result of oxygen lack. Some are less responsive than others, but the rule seems to be that when a tissue becomes anoxic the capillary bed becomes larger. In many cases dilatation is accompanied by increased permeability, so that edema also occurs, but in the experience of most investigators abnormal leakage is not an essential companion of larger capillary diameter unless the change is extreme.

Our concern today is with the lung capillaries. In spite of evidence purporting to show it, there is no reason to believe that these capillaries possess active powers of contraction and dilatation as is the case with practically all the systemic vessels. This does not mean that their diameter does not change, nor that at times there are capillaries that are not conducting blood and that may later be filled by a moving current. These changes are, I believe, passive and depend on variations in the output of the right ventricle or a rise in pressure in the pulmonary veins. The capillary net in the

lungs is for the purpose of gathering oxygen to serve the entire body and for eliminating all the carbon dioxide produced. The vessels lie in a tissue so delicate that it is structurally almost the foam the ancients believed it to be, and is at the same time highly elastic. The lungs must meet the needs of the body when the cardiac output is 4000 cc. a minute and when it rises abruptly even to 30,000 cc., and this result is best obtained if the vascular bed is large enough for the greatest needs, and so arranged as to give all parts of it a practically equal chance to receive increased amounts of blood instantly and without any adaptive opening reaction (Fig. 1).

That the lung capillaries do not dilate adaptively as a result of oxygen lack does not exclude them from the second effect of anoxia, — namely, increased permeability, — and anoxia does make these vessels leak abnormally, a fact all too apparent as one watches the slow progress of pulmonary edema or, perhaps even more frequently as one looks at the lungs at autopsy.

It is necessary to appreciate certain anatomical and physiologic facts and deductions about the lung capillaries. The situation to be examined is provided by a diagram (Fig. 2) constructed

FIGURE 2. *Diagram of Certain Fundamental Conditions That Must Be Considered in Connection with the Formation and Removal of Pulmonary Transudates and Exudates.*

for the lungs on the basis of what is known to be operative in the case of systemic capillaries. In this diagram there is a capillary containing blood with a normal plasma protein content of 7 per cent, and this protein exerts an osmotic pressure — the colloid osmotic pressure of

asma of 25 to 30 mm. of mercury. In most systemic capillaries this force, which attracts water into the vessels, is opposed by the capillary blood pressure derived from the left ventricle and of about the same magnitude. There is thus a balance of forces that controls movements of water and dissolved salts through the capillary endothelium. In the lungs the colloid osmotic pressure drawing in water is necessarily 25 to 30 mm., but the opposing capillary blood pressure is not known. It must be low, and 10 mm. is a fair value. This means that in the lungs relative dryness of the tissue is substantially safeguarded and that under normal conditions extravascular fluid is in reality intracellular fluid. There are, however, local disturbers of this balance. The walls of the lung capillaries are separated from the alveolar air by a single layer of extremely thin epithelial cells. At each normal inspiration the pressure in the trachea becomes negative (-3 mm.), and this effect extends through the bronchi into the alveoli. At the end of inspiration, air having entered the alveoli as a result of atmospheric pressure, the intra-alveolar pressure becomes zero and rises slightly during expiration. This means that for outward filtration of water during inspiration an element of suction is added, and thus the filtering pressure is above 10 mm., and since a negative intrapulmonic pressure of 50 mm. may readily result from the obstruction of the trachea, it is clear that high filtering-out pressures may accompany half the respiratory cycle over long periods of time. It is true that the expiratory phase of breathing reverses the state of affairs, and that with the lung tissue wholly normal mechanical conditions that would result in the production of significant capillary leakage do not occur. But one must bear in mind that there is a single restraining influence for keeping water in the lung capillaries, which is fixed in the sense of being unalterable by local changes — the concentration of the blood proteins and their colloid osmotic pressure.

The other factors in the diagram are changed more or less readily, and all more readily in the direction of production of edema than against it. Thus, the permeability of the capillary endothelium may be increased by anoxia and by the action of drugs. The pressure in the lung capillaries is hard to disturb because of the immense area of the vascular net and the readiness with which expansion can be induced, but increases in pulmonary capillary pressure accompany cardiac disease, particularly while the right ventricle is still competent and a high-pressure head for outward filtration of fluid is maintained. This pressure may be enhanced by increased negative pressure in the alveoli during dyspnea. The human system depends for lung dryness on what Meltzer² years ago termed "a factor of safety" inherent in the predominance of osmotic retention of capillary water. This "safety"

is assailable from a number of directions, and the attack is never achieved by a single one of the assailing forces but practically always by many of them. Of the factors leading to edema, increased permeability of the lung capillaries is by far the most important and of all the possibilities for inducing it, anoxia is infinitely the most frequent.

There are two other items in the diagram that have not been mentioned. The first of these is the negative intrapleural pressure. Graham³ in 1921 expressed the belief that prolonged increase in the negative intrapleural pressure may suck fluid through the pleura and cause pleural effusion. This is true. Indeed, it has been shown that apparently normal men subjected to hard physical exercise accumulate pleural transudates. It is apparently the increased breathing of the exercise that does this, through the sucking action of lowered intrapleural pressure during vigorous inspiration.

The final component of the diagram is a lymphatic. Wherever lymphatics are found in the body their principal function is the carrying off of small amounts of protein that have left the blood capillaries. In addition to this regular function, the lymphatics take away other things in the tissues not readily absorbed by the blood vessels, among these being bacteria, foreign particles of many varieties and the detritus accompanying inflammation. The distribution of lymphatics is most profuse in parts of the body that are essentially surfaces between the interior of the body and the outside world. A well-known example is the extraordinary number and size of the lymph capillaries in the nasopharyngeal mucosa and in the mucosa of the female genital tract. In these regions, in addition to the constant possibility of infection, with the necessity of removing highly proteinized exudates, there are rhythmic periods of edema due to transudation of fluid containing much protein. The lungs seem to be free from any need to be constantly cleared of excess tissue fluid, but it is a fact that they are as profusely supplied with lymphatics as is practically any tissue in the body. Lymphatics are constantly seen in lung sections, but one has a poor idea of their number or extent and of their ability to rid the lungs of fluid. Over the surfaces of the arteries, veins and bronchi are lymph vessels, obviously large vessels. Their ends do not reach into the actual alveolar walls but stop as blind terminals in the walls of the alveolar ducts. An idea of the extent and capacity of the lung lymphatics is gained by a reconstruction of a typical plexus about a pulmonary vein (Fig. 3).

In spite of this profusion of lymph channels, it is puzzling to find that the arrangement for delivering their contents into the blood is curiously inadequate. The fact is that all the lymph from the lungs except a very small amount from the upper part of the left lung empties into the right sub-

clavian vein by way of the right lymphatic duct, which is usually a short tube not more than a millimeter in inside diameter. This vessel is an astonishingly small bottleneck at the delivery end of a large reservoir for accumulating proteinized and waste-containing fluid.

Let us now consider the bearing of these and other matters on asphyxia of the lung capillaries.

FIGURE 3. *Plexus of Lymphatics about a Pulmonary Vein (x15) (reproduced from Miller¹ by permission of the publisher). This particular vein was situated in an interlobular septum.*

Their endothelium is in the peculiar situation of receiving oxygen directly from the air, not at second hand from the blood. From the latter, all that the endothelium can gain is the precarious supply still remaining in the venous blood. This makes the lung capillaries dependent on the oxygen content of the alveoli in whose walls they lie. The body in general gets oxygen through the entire absorbing surface of the lungs, but the situation of the alveolar capillaries is not so safeguarded, and as transudation from these vessels begins they are steadily more and more widely separated from their oxygen supply.

To illustrate, there is employed a section of lung where exudate is forming and has formed (Fig. 4). One should observe the clear space under the pulmonary epithelium, which has been pushed loose in a continuous sheet. There is exudate in the alveolus, which may interfere with ventilation, and a layer of fluid under the epithelium and between it and the capillary wall. There are three possible ways of getting rid of this exudate. It may drift up through the air passages and be coughed out, may be broken down by enzymes and absorbed into the blood, or may drain off through the lymphatics. This last pathway is immediately available for interstitial exudate, which, as it accumulates in the alveolar wall, must eventually surround a capillary lymphatic terminal and enter it, to move slowly toward the right lymphatic duct through the enormous lymphatic network described, in every case traversing at least one lymph node. It is not surprising that when one causes continuous and copious leakage of lung capillaries, one finds bronchi

and blood vessels surrounded by rings of fluid. In such a case, as is illustrated in a low-power photomicrograph (Fig. 5), most of the thin-walled intercommunicating lymphatics have apparently been ruptured, and lymph drifts along the blood vessel as a grossly visible sleeve of dilute blood plasma, which may or may not reach the narrow neck of the funnel — the right lymphatic duct.

All this indicates clearly enough that the lung are not provided with any too adequate means of getting clear of exudates once they are present, and obviously exudates interfere profoundly with the entrance of air into alveoli and the passage of oxygen into lung capillaries. So in the lungs as well as in the respiratory center anoxia begets anoxia.

How vulnerable the lungs are to oxygen lack can be approximately shown by an example. If the lungs of a normal dog are ventilated artificially so that the mechanical factors in breathing are held constant and lymph is collected from the right lymphatic duct, the flow of lymph increases and the lymph becomes bloody when the oxygen in the air is reduced to 8.5 per cent; if one shifts back to 100 per cent oxygen, the flow soon falls to normal and the red cells disappear.⁴ It must be realized that this experiment has to be a rather crude one, carried out on a curarized animal under constant conditions of artificial respiration, which inflates the lungs through positive pressure and allows expiration to occur passively. Positive-pressure ventilation does not reach the alveoli

FIGURE 4. *Section of an Exudate-Containing Lung (x345) (reproduced from Miller¹ by permission of the publisher).*

The epithelium lining the alveolus in the center of the figure has been pushed off as a continuous sheet. Certain of the cells are more swollen than others. The alveolus in the upper right of the figure shows clearly the epithelium before and after an exudate has raised it from the surface of the alveolar wall.

throughout the lungs with anything like the efficiency of the negative-pressure ventilation of normal breathing. It is thus quite probable that the transudation reflected in the lymph comes from parts of the lung that are receiving little or none

of the oxygen-poor mixture employed, and that the capillary endothelium of the lungs is much more resistant to oxygen lack than the experiment indicates. But even if this is the case, it is obvious that parts of the lungs have been affected and that a return to adequate oxygen in the air is followed by prompt restoration to normal. If, however, the experiment is carried out more slowly and abnormal capillary leakage is continued for some time, restoration of normal conditions through the use of oxygen is greatly delayed or does not occur during the experiment. Furthermore, if the pressure in the lung capillaries is increased by tightening a clamp on

oxygen in 1914, when I entered the Peter Bent Brigham Hospital as a house officer, was negligible, but this entire lack of reliance on oxygen has given way to a better appreciation of what it can accomplish. The reasons why there is still too little use of oxygen are as follows. In the first place, anoxia is essentially progressive. If the physician begins to use oxygen when he is sure that it is needed, he has incurred a handicap that is usually insurmountable. The time to begin to use oxygen is before there is any certainty it is needed. Secondly, the present methods for administering oxygen are expensive and inefficient. It will probably be

FIGURE 5. Section of the Lung of a Dog with Severe Exudation ($\times 18$)
Note the rings of relatively clear fluid surrounding the blood vessels and bronchi.

the pulmonary veins when oxygen-poor air is used for ventilation, the lung lymph changes in a very short time into what is practically blood.

One may be deceived in regard to the onset of lung edema by the fact that the lungs are so much larger than the resting subject requires. If the process begins in a dependent part of a lobe and transudate travels up bronchi and obstructs neighboring bronchi, no attention is paid to it until the patient, at rest and so requiring the least possible oxygen, takes a distinct turn for the worse. When this happens, the lungs, as receiving structures, where gas exchange can occur readily, are greatly reduced in functional size and the safety inherent in their normal oversize is lost. The probability is that the condition will progress further, not only by local spread of excess fluid in the lungs but also because as anoxia increases the efficiency of the respiratory efforts often becomes less.

It is my task to speak of but one of the measures for combating anoxia. It is the obvious one — administration of oxygen. The therapeutic use of

a long time before oxygen therapy is inexpensive, but that is not of so much moment as is inefficiency.

Pure oxygen has five times the power to penetrate exudates and reach anoxic parts of the lungs and the blood going through them that air oxygen has. Pure oxygen breathed continuously for eight to twelve hours is of itself irritating to the respiratory passages, but minor interruptions from time to time are enough to dispose of this danger, which is not a potent one unless oxygen is breathed under a pressure of two to three atmospheres. Oxygen tents often do much for patients, but they are leaky, inefficient affairs in which the oxygen concentration is usually well below 60 per cent. Mask administration of oxygen has improved, and if the experience gained during the war is utilized it can be carried much farther. Lastly, there is a failure to realize the possible advantages to be gained even from poorly administered oxygen in many ordinary conditions. For example, there is no drug that gives such great subjective relief or such valuable rest in dyspnea as does morphine, but this drug dampens

clavian vein by way of the right lymphatic duct, which is usually a short tube not more than a millimeter in inside diameter. This vessel is an astonishingly small bottleneck at the delivery end of a large reservoir for accumulating proteinized and waste-containing fluid.

Let us now consider the bearing of these and other matters on asphyxia of the lung capillaries.

FIGURE 3. *Plexus of Lymphatics about a Pulmonary Vein ($\times 15$) (reproduced from Miller¹ by permission of the publisher). This particular vein was situated in an interlobular septum.*

Their endothelium is in the peculiar situation of receiving oxygen directly from the air, not at second hand from the blood. From the latter, all that the endothelium can gain is the precarious supply still remaining in the venous blood. throughout the lungs with anything like the efficiency of the negative-pressure ventilation of normal breathing. It is thus quite probable that the transudation reflected in the lymph comes from parts of the lung that are receiving little or no

many points of dissimilarity between the two diseases, which are sufficient to prove that they are separate though allied infections.

One of the striking differences between yaws and syphilis is that in yaws the infection is usually, if not always, extragenital. Again, in the secondary period there are no lesions of the mucous membranes, the absence of vaginal mucous patches probably accounting for the failure of infection by sexual intercourse. Another difference is the absence of intrauterine infection in yaws, there being no lesions in children that suggest congenital syphilis.

Yaws is a milder infection than syphilis because it does not affect to any appreciable extent the vital structure of the body. It is doubtful whether the viscera are affected by yaws, and lesions of the cardiovascular and central nervous systems are mild compared with those of syphilis. The statement is often made that no one seems to die of yaws, although in the late stages severe deformities may result from lesions of the skin, mucous membranes, bones, tendons and joints. The lessened tendency for yaws to attack the blood vessels is seen in histologic sections of cutaneous lesions. These do not show the same tendency as the lesions of syphilis to produce endarteritis. Yaws also yields to treatment more rapidly than does syphilis.

There are differences between the immune reactions of yaws and of syphilis, but eventually, at times after ten years, there is a complete cross immunity between the two diseases. This is well shown in the island of Guam, where most of the natives are immune to syphilis, since they have been infected as children with yaws.

PINTA

Pinta, like many other tropical diseases, has numerous local names. In Mexico, for example, it is called *mal del pinto*, in Colombia *carate* and in Venezuela *cute*. Pinta is an infectious disease mostly confined to the American tropics. It is caused by a treponema that is morphologically identical with the organism causing syphilis and yaws.

For many years the disease was thought to be due to a fungus, this theory persisting for eleven years after it was first shown that the serologic tests were positive in a large proportion of cases. By 1930, it was shown that the serologic reaction with both complement-fixation and flocculation tests in the pigmentary stage was almost 100 per cent positive. This was comparable to the serologic changes in syphilis and yaws. After the discovery of the causative treponema in 1937 by Armenteros and Grau Triana, the fungus theory was discarded.

The greatest incidence of pinta is found in Colombia and the southern half of the Republic of Mexico. A careful survey made a few years ago in Mexico disclosed the presence of over 270,000 cases. The

disease affects chiefly the dark-skinned races, including Indians, Negroes and those of mixed blood. It is rarely seen in Whites. This fact helps to substantiate the claim that the disease is caused by personal contact and not by the bite of an insect or other arthropod. At least there is no definite knowledge concerning a possible insect vector.

Soon after the discovery of the causative organism, Leon y Blanco went to Mexico and proved that the disease is inoculable in man and that syphilis gives no immunity to it. The same investigator showed that a primary scaly plaque represents the initial lesion, which is often followed by nondescript secondary lesions of the skin. Eventually, the pigmentary stage ensues and lasts for years or decades. Previous to the discovery of a possible primary and secondary stage, the pigmentary disturbances were thought to constitute the entire picture of pinta.

The pigmentary stage consists essentially of slaty-blue patches appearing especially on uncovered parts as freckles or diffuse areas. Eventually a partial depigmentation appears, and if untreated the process in some cases continues until the patches are completely devoid of pigment. The eruption is then indistinguishable from ordinary vitiligo and is a permanent defect, the normal pigment never returning.

The serologic reaction in pinta is positive in nearly 100 per cent of cases in only the late (pigmentary) stage, whereas in the primary stage it is negative and in the secondary stage, when recognized, is said to be positive in 60 per cent of cases. In this regard pinta differs from the other two treponematoses, syphilis and yaws, in which the strongest positive reactions occur in the secondary stage and gradually lessen in the late stages. As a rule, there are no abnormalities in the spinal fluid in pinta.

The typical slate-blue color is due to the large number of melanophores in the cutis and not, as was originally thought, to the action of fungi.

Pinta, in the vast majority of cases, is an essentially harmless disease, except for the cosmetic deformity, which in some cases is severe. Those who suffer from pinta are apparently able to work as hard as are others who are not affected with the disease.

CUTANEOUS LEISHMANIASIS

Cutaneous leishmaniasis may be divided into the type seen in parts of the Old World and known as Oriental sore, Aleppo boil, Biskra button and so forth and the type appearing in the Western Hemisphere, known as American or mucocutaneous leishmaniasis. Both these types are caused by parasites, called "leishmaniae" in honor of Colonel Sir William Leishman, who first discovered them in kala-azar. The parasites causing the two types are morphologically indistinguishable in microscopic preparations made from scrapings and in cultures.

the respiratory center and thus promotes anoxia. There is no reason why the use of oxygen with morphine should not allow all possible benefit from the sedative without the progression of anoxia. Similarly, after operations, particularly in elderly patients with fairly rigid chests and pain on breathing that still further restricts respiratory movement, oxygen therapy may for a time permit the economy of lung movement that the patient involuntarily provides, and the use of a much needed sedative may be robbed of some of its danger.

It would be possible to multiply such illustrations indefinitely. These are enough, and they, with all that has been said above, may help to enforce further

the two principles that the laboratory has learned: the master words in oxygen therapy: anoxia begs oxygen, and if real benefit is to be expected from oxygen, it should be used before the need is certain.

TROPICAL DISEASES OF THE SKIN*

HOWARD FOX, M.D.†

NEW YORK CITY

IN THIS paper will be discussed five diseases in which cutaneous manifestations constitute either the whole clinical picture or an important part of it. Three of these diseases, yaws, pinta and verruga peruana, are almost entirely confined to the tropics, and the other two, cutaneous leishmaniasis and leprosy, are at least more prevalent in tropical than in temperate climates.

The present interest in tropical diseases is mainly due to the possibility of their being contracted by the members of our armed forces. Of the diseases in question, the likeliest ones to affect our soldiers and sailors are cutaneous leishmaniasis and leprosy. It is almost certain that a few men at least will contract these diseases, although in the case of leprosy there may be no active manifestations for a number of years after their return to the United States. Information about tropical diseases of the skin will also be of value to medical officers whose duty it may be to take care of native populations, both during and perhaps for some time after the war.

YAWS

Yaws (*frambesia tropica*) is an infectious disease caused by *Treponema pertenue*, an organism that is morphologically identical with *T. pallidum*. The disease occurs almost exclusively in dark-skinned races, especially Negroes. The fact that the white man rarely suffers from yaws is probably due to personal hygiene and not to any racial immunity. The geographic distribution of yaws is widespread and includes parts of equatorial Africa, many islands of the Pacific, Burma, Thailand, some islands of

the West Indies and tropical parts of South America. The disease is contracted most often in childhood usually by personal contact, although in some cases the infection is transmitted directly by certain flies. The initial lesion or so-called "mother yaw" may not be observed. It does not remotely resemble the chancre of syphilis, and is merely the largest lesion of the type of the ordinary secondary or frambesiform eruption.

The typical eruption of yaws — frambesiform — begins as small papules that tend to coalesce, soften and discharge a fluid that forms typical amber-colored crusts. It does not resemble any ordinary eruption of syphilis but rather suggests an impetigo. The eruption lasts for months up to a year or two and disappears spontaneously without leaving any permanent trace. Another characteristic eruption is a hyperkeratosis of the soles, called "crab yaws" by the natives of the West Indies. The term is used because the affected persons walk like a crab, owing to soreness caused by secondary infection. The eruption is not due merely to walking barefoot, since barefooted natives who suffer from syphilis do not often present this characteristic eruption.

There are two frequent manifestations of early syphilis that have never been observed in yaws. They are iritis — or iridocyclitis — and alopecia, including both a diffuse thinning of the hair and the patchy so-called "moth-eaten" type so characteristic of syphilis.

There are four features that yaws and syphilis have in common. In both diseases the causative organisms are morphologically identical, both of them give the same serologic reactions, both yield to arsenamine and allied drugs and to bismuth, and in both the late destructive tertiary lesions are clinically indistinguishable. There are, however,

*Presented at the annual meeting of the Massachusetts Medical Society, Boston, May 23, 1944.

†Professor emeritus of dermatology and syphilology, New York University School of Medicine.

Oroya fever is a most serious disease, with an average mortality of about 40 per cent, and presents the symptoms of pernicious anemia, with a sudden and tremendous drop in the red-cell count. *Veruga peruana*, after the stage of incubation, is also accompanied by febrile symptoms and anemia, but the latter is of the simple type. After a period of several months, an eruption appears and the patient is then on the road to recovery. The eruption is a unique one and consists of lesions that resemble pyogenic granulomas, senile angiomas or a general sarcomatosis. The eruption disappears spontaneously in a few months, and the patient is thereafter immune.

The causative organism is seen in the red cells of the peripheral blood in varying numbers (from one to ten or more). In culture it appears as rod-like bodies or as cocci.

The vector was proved to be night-flying species of *Phlebotomus*, whose habitat corresponds exactly to the areas where the disease is contracted. This is in deep ravines at an altitude between 2800 and 9000 feet. Most of the inhabitants of these ravines contract the disease in infancy or early childhood, when it causes only mild symptoms. There is no known specific treatment. Prophylaxis is all important. Townsend states that no one ever contracts the disease in Peru unless he has spent one or more nights in the infected ravines.

LEPROSY

Leprosy is a serious disease that carries an undeserved stigma. This is partly due to the Biblical descriptions of a disease that was in all probability the same as the one now called leprosy. The disease has a world-wide distribution; although it exists in cold and temperate climates, its greatest incidence is in the tropics. It has been roughly estimated that there are 3,000,000 lepers in the world, about 30,000 of whom are in the Western Hemisphere. In the United States, it is estimated that there are 1000 or more cases, and in New York City there are always 25 or more cases known to the health authorities. All the latter are imported cases.

Contrary to popular belief, leprosy is not highly contagious. To contract the disease it is usually

necessary to be exposed to it for long periods, especially in hot and humid regions. The method of transmission is not known, although infection of the nasal mucosa by the fingers is thought in many cases to be the cause. The disease is apparently not contracted by sexual intercourse.

Leprosy affects all races and both sexes and is oftenest contracted in the fifth to the twentieth year of life. The disease is neither congenital nor hereditary. It is undoubtedly caused by *Mycobacterium leprae* (Hansen's bacillus), even though the postulates of Koch have not been fulfilled. The disease is strictly confined to man and does not affect any of the lower animals.

The terminology of leprosy lesions has been the source of considerable confusion. At the present time, one speaks of the two essentially different types as lepromatous, — formerly called nodular, — and neural, which can be subdivided into pure neural, maculoanesthetic and tuberculoid. The neural type has the signs and symptoms of a peripheral neuritis, the disease not affecting the brain or spinal cord. The neural type is the one oftener seen in the tropics and is decidedly more favorable in prognosis than the lepromatous type. It may cause severe mutilations, but the disease may become arrested and the patient live for decades thereafter.

One of the numerous problems to be settled in the future is why the disease is transmissible in some regions and not in others. For instance, Louisiana, Texas and Florida are now practically the only endemic centers in the United States. On the other hand, although there are always lepers in New York City, there is no case on record in which a person has contracted the disease in or near this city. In every case the person has spent more or less time in a part of the world where the disease is endemic. It therefore seems eminently proper to allow lepers in New York City to go at large, although they must report at intervals to the local health authorities.

The only way to eradicate leprosy is by segregation. In my opinion, there is as yet no specific remedy for the disease.

140 East 54th Street

Oriental sore has a widespread geographic location, including Africa, Asia and parts of Europe. In Africa it occurs along the Mediterranean coast. In Asia Minor it is especially rife in Syria, Palestine and Armenia. It is endemic in the southern and eastern parts of Asia, and in Europe it occurs in Greece, Italy, Sicily, Cypress and Crete. This incomplete list shows numerous areas in which our armed forces are exposed to this disease.

Oriental sore may be contracted either by the bite of some species of sandfly (*Phlebotomus*) or by personal contact, as from one child to another. The disease is also occasionally transmitted by the common housefly. In certain areas dogs are infected, especially about the snout, and constitute a reservoir for the parasites.

The incubation period of Oriental sore varies from a few weeks to many months or at times a year. The eruption begins as small papules that enlarge and form a buttonlike plaque several centimeters in diameter. Eventually it becomes an ulcer covered with adherent crusts. It does not suggest the appearance of a boil, and the term "Aleppo boil" is therefore a misnomer. Healing is usually followed by scars, which may be disfiguring. There may be a single lesion or several, as many as a hundred or more having been observed.

Oriental sore is usually confined to the skin and as a rule occurs on the uncovered parts of the body. In the vast majority of cases it heals within a year as the Turkish name *habel-seneh* ("button of one year") indicates. In rare cases the disease lasts for many years. As a rule, when the eruption clears spontaneously or from treatment it is followed by permanent immunity. In extremely rare cases there is a recurrence. The disease is purely a local one and causes no constitutional symptoms.

The eruption must at times be differentiated from that of syphilis, tuberculosis, blastomycosis, ecthyma, bromoderma and tropical and other ulcers. An unquestioned diagnosis depends on finding the parasites in smear preparations—stained by Wright's method—or in cultures. In difficult cases, help has been given by intracutaneous tests of material from killed parasites.

Innumerable methods of treatment have been tried, with varying success. Excellent results have been obtained with x-rays and grenz rays, which, however, are not generally available. Care must be used with escharotics, since the disease is not a serious one and constitutes only a cosmetic defect. *Excellent results have been claimed by freezing with man rarely suffers from it.* Prophylactic treatment in personal hygiene and in the use of insect repellents. The geographic distribution with forty-five holes to and includes parts of equatorial and subequatorial regions of the Pacific, Burma, Thailand, *leishmaniasis*

Peninsula. The disease in the majority of cases is an occupational one, and is seen most often among foresters in Brazil, workers on tea plantations in Paraguay and chicle pickers in Guatemala and Yucatan. It is probably caused as a rule by the bite of some species of *Phlebotomus*, although infection by personal contact is possible. The causative organism is identical in appearance with that of the other types of leishmaniasis.

The American type differs from Oriental sore in its tendency to last for years and to attack the mucous membranes of the nose and throat, as it does in 15 to 20 per cent of cases.

The cutaneous lesions consist of one or more ulcers, occasionally a hundred or more. At first glance they appear to be nondescript, but they usually have a halo that is red and edematous. Lesions of the nose and throat, if present, usually follow cutaneous lesions by years and may be extremely deforming.

Treatment of cutaneous lesions by tartar emetic gives satisfactory results, but this remedy is not so efficient for lesions of the mucous membranes.

VERRUGA PERUANA

Verruga peruana (bartonellosis) is now known to be one phase—the other being Oroya fever—of a disease that has probably existed in Peru for centuries. It has recently been observed in both Colombia and Ecuador.

Little was known of *verruca peruana* until 1870, when a railroad was built over the Andes. A violent epidemic resulted in which 7000 laborers died and 100 American and British engineers contracted the disease, half of them dying of it. In 1885, a brilliant young Peruvian medical student allowed himself to be inoculated with the harmless *verruca peruana* and died of severe Oroya fever. This convinced the Peruvian physicians that the two types probably represented the same disease. In 1913, Strong and others forming a commission from Harvard University visited Peru and concluded erroneously that *verruca peruana* and Oroya fever were separate diseases. In 1909, the causative organism, which is now thought to be a rickettsia, was discovered by Barton and was successfully cultured in 1926 by Noguchi and Battistini. Monkeys were inoculated by Noguchi with a culture from a case of Oroya fever and *verruca peruana* resulted. A year later, Mayer and Kikuth in Hamburg inoculated monkeys from a case of *verruca* and produced fatal Oroya fever. There was also a physician in Lima who accidentally inoculated his finger while giving a transfusion to a patient dying of Oroya fever. Fortunately he developed *verruca peruana* of the harmless type and recovered. From these facts it seems clear that *verruca peruana* and Oroya fever are different phases of the same disease.

misuse of the Snellen test in the public schools of Massachusetts since 1906 are illuminating:

Teachers, having to rely on an instruction sheet that is furnished with the chart to guide them, often failed to observe one or more fundamental requirements, such as making sure that the eye not being tested was covered, or that the chart was placed where illumination would be adequate, and without glare from reflected light.

Letter charts were used, which children committed to memory.

The use of letters precluded the vision testing of kindergarten and first-grade and second-grade children, most of whom were, for the purposes of the test, illiterate.

The experience gained by school authorities during the first few years suggested the need of measuring the vision of younger children. They appealed to the State Department of Education, which in turn requested the Department of Public Health to recommend a test chart for illiterates. A subcommittee of the Council on Public Health, made up of Drs. David L. Edsall and William J. Gallivan, in 1915 recommended a chart (Fig. 1) for the use of teachers testing illiterates, which since 1917 has been distributed on request to the schools of the Commonwealth. This chart,

BOSTON TEST CHART

20 FEET

FIGURE 1.

The Boston Test Chart differs from other standard charts in that symbols on the 30 and 20 foot lines are spaced more than 5 minutes apart.

which is based on the Snellen scale, was partly devised by Snellen himself¹ as a test for illiterates, using three parallel lines. Pergens² later joined these

lines on one side by a line of equal width. This is the most practical test object for use in schools, and moreover its use should not be limited to illiterates. It has three outstanding features. Firstly, after a short drill, conducted as a game, the vision of

FIGURE 2. Old Method of Occlusion.

This method, although dependable, required an extra teacher.

children over two years of age may be accurately tested with it. Secondly, it is not to be compared with capital letters, which when made as uniform as possible are visible from different distances.³ It therefore conforms more nearly than do other objects to the physiologic requirements for a test object. Finally, if the symbols are selected by the teacher conducting the test, as I⁴ have recommended, even a small chart, such as that furnished by the State Department of Education becomes unlearnable.

A test chart that can accomplish so many things faithfully is no mean device. Competent ophthalmologists during the last quarter of a century have filled many pages of printed matter with a variety of unique test symbols, all carefully drawn to the Snellen scale, but none of these, so far as I know, compare with the Pergens symbol. As for some ludicrous and impractical technics suggested to prevent school children from memorizing test letters, the least said of them the better.

In a previous paper, I⁴ suggested a technic for testing vision of school children. It required two

THE GOAL OF AN EYE-HYGIENE PROGRAM FOR SCHOOL CHILDREN*

JAMES J. REGAN, M.D.†

BOSTON

THE title of this paper implies that there should be some sort of program directed toward the maintenance of eye health in all schools. Such a program need not be expensive, requiring equipment, personnel and time, nor so extensive as to include a complete eye examination by a competent ophthalmologist, let us say three or four times during the child's school life. Its object is best expressed as a consciousness on the part of school administrators, teachers and pupils alike of the value of normal, comfortable vision to progress in health and education, coupled with a desire for positive action. It can take such form as facilities available in the locality permit and the support of the local school authorities provide. The program may range from tried and true yet simple procedures, such as annual medical inspection and tests of visual acuity for distance (the Snellen test), to the complete and periodic examination of each child by a competent ophthalmologist. It may be extended to include psychophysiologic studies of certain groups of children such as those presenting symptoms of reading disability—formerly referred to as congenital word blindness. It may include provision for instruction concerning the care of the eyes (personal hygiene) and accident prevention, and may stress the importance of paying more attention to the eyes during the routine medical inspection. It may furnish special educational facilities for the visually handicapped child. It may provide for better school buildings, artificial illumination, desks, printing of schoolbooks, as well as other printed and mimeographed material, window shades and wall paint. It may provide for good blackboards, properly located and cared for, to ensure maximum contrast and a minimum of glare from reflected light, and proper chalk, and may even place minimum limits on the size of letters and figures to be written on the blackboards.

Such a program may be expanded or contracted from year to year, reflecting any new advances in the fields of education, psychology, ophthalmology, architecture and engineering, and would survive curtailment of the school budget. It would even permit, occasionally, trial of newer technics of unproved value, without being seriously or permanently affected.

The consciousness of the value of good vision, which is the cornerstone of the program, must be

laid in teacher-training institutions. All elementary-grade and intermediate-grade teachers should have some knowledge of visual psychology, as well as of ophthalmologic anatomy, physiology and hygiene. They should be instructed in objective and subjective signs of eyestrain, and should be so well versed in a dependable vision-testing technic that their findings will be accurate. Because the teacher has the unique opportunity of observing the child at work every hour of the school day throughout the school year, any eye-hygiene program that does not include the teacher will fall far short of its goal. There is a mutual benefit to be derived. A child who sees well and comfortably is less of a drain on the teacher's time and patience than the child with poor vision.

Historically, it is true that teachers, rather than physicians, were responsible for the enactment of legislation in Massachusetts that, since 1906, has required that every child in the public schools have a vision and hearing test at the beginning of each school year, and that the class teacher conduct the tests. The prescribed vision test is one designed to measure the acuteness of distant vision, and nothing more. Admitting that it would be better to know more than is now known about the visual efficiency of school children, I am certain that it is wrong for any individual or group to challenge the value of the results of the Snellen test, provided that it is properly conducted. This test is simple and reliable, and involves no expense; it takes a minimum of school time; it requires no special equipment, eliminating such factors as cost, transportation, breakage and replacement; and it brings about the discovery of about 85 per cent of children with visual and other eye defects. It might, indeed, discover 10 per cent more, if it were supplemented by a simple test for detecting farsighted children, who have normal distant vision but find near work difficult. For these reasons, the value of such a test should be defended against attacks by groups, many of whom have equipment to sell and who, in order to impress school authorities with the superiority of their devices for discovering rare and usually unsymptomatic conditions, such as extraocular muscle imbalance, suppression or alternate fixation, poor stereopsis and astigmatism, feel obliged to declare the Snellen test worthless and the school system that uses it archaic.

The test is absolutely dependable, but educational authorities seem to have little regard for the valuable information it furnishes, and consequently bother little about the manner in which it is conducted. The following examples of the

ads only to the third row, it is recorded as 20/30; only to the second row, as 20/40; and if only the top row, as 20/50. He should be made to read at least two symbols on the lowest row that he can see in order to get credit for the row. If he cannot see the top row, he should be told to approach the chart — always with one eye covered — and stop where he can see two symbols on the top row. If, for example, he walks to within 5 feet of the chart, his vision is recorded as 5/50.

FOLLOW-UP

Obviously, much of the time spent by school physicians and nurses in inspecting children's eyes and by teachers in testing their vision would be wasted

To recapitulate, the cornerstone of a workable, effective eye-hygiene program for school children rests on the development of a consciousness within the school system, especially among the teachers and pupils, of the value of normal vision to the progress of health and education. This may be developed through an educational program in the schools, sponsored by a joint committee of the State Department of Public Health and Department of Education. The committee's function should be to stimulate surveys by the school authorities in cities and towns throughout the Commonwealth. Interest might be created by first presenting to the heads of all school departments a copy of the statute requiring an annual vision

FIGURE 5. Method of Using the Test Chart.
The pointer should not mark the chart or cover any part of the symbol.

if some provision were not made by the school to follow up cases of defective vision and other eye conditions discovered or suspected, soon after a notice has been sent to the parent or guardian. Expert medical advice is available in normal times to school children of all economic groups in the large cities; in small towns and in rural communities, this presents a problem. The optometrist may be the only person available to provide eye care of any sort, but this service, even though limited in scope, may suffice for a large percentage of children with refractive errors, especially myopes. The more complicated cases should be brought to the nearest ophthalmologist or eye clinic by the parent, the school nurse or some other designated person. The disposition of indigent cases should be the concern of the school principal or physician.

* * *

test, together with an authoritative statement regarding the importance of conducting the tests properly, as well as obtaining relief for children early in the school year for those found defective.

With this accomplished, such a committee might arrange an outline for teachers, giving symptoms of eyestrain that may warrant a medical eye examination. Often a child with 20/20 vision in each eye suffers from sties, crusted red lids, watery eyes, irritated eyes or headache, especially after doing close work. Many of these children are farsighted, and if their accommodation is good, the Snellen test will not screen them out, but they suffer from and dislike close work, and are frequently truants. The committee might suggest a simple test for screening out this type of child at the time of the annual

teachers to conduct it, because the occluder used was a card measuring 3 by 5 inches (Fig. 2), and if the children were allowed to hold it and the better

FIGURE 3. *Types of Occluders Used by the United States Navy. The newer form (above) permits observation of squinters and prevents artificial reduction of the size of the pupil by looking along the edge of the opening.*

eye was occluded, most of them peeked. The technic has been modified by substituting the more efficient occluder used by the Medical Department of the United States Navy (Fig. 3).

TECHNIC OF TESTING

The chart should be hung on an easel, black-board or other device, near a window (but not in direct sunlight) and at right angles to it; it may be hung in the window casing. If one end of the room is brighter than the other, the chart should be placed at the brighter end. Its height should be about the level of the average child's head. If there is glare* from windows between the chart and the child, the lower half of the window may be covered or the shade drawn. This is rarely an obstacle unless the child, standing at the 20-foot line, is abreast of a window.

A distance of exactly 20 feet should be measured from the chart along the windowed wall, a thumb-tack or chalk mark being placed on the floor or wall every 5 feet.

The occluder may be made of heavy cardboard, plastic or Masonite. The latter two materials are washable, even in antiseptics (a 1:1000 aqueous solution of Zephiran Chloride may be used). The occluder is held in the left hand with the opening in front of the right eye, which should always be tested first (Fig. 4). If the child wears glasses, he should be asked whether his vision is better with or without them. If it is better with glasses, the test should be made with them on, a notation to that effect being made on the record. If the vision is better without glasses, the test is made with them off.

*Glare is a brightness within the field of vision of such excessive character as to cause discomfort or interfere with vision

The record will be more complete if the vision is tested both with and without glasses, in which case the vision of the naked eye is tested first. (If the vision is better without glasses, it should not be concluded that they are not correct; instead, re-examination should be advised, especially if the glasses are more than a year old.) After the right eye has been tested, the child holds the occluder in the right hand with the opening in front of the left eye, and that eye is tested.

When pointing to the symbols the examiner should not stand on the window side of the chart, lest a shadow be cast upon it (Fig. 5). The point of a pencil should not be used, since it may mark the card. The pointer must not cover any part of the symbol. A symbol on the top row is selected, and the child is told to semaphore the direction in which the arms of the symbol point. If his direction is correct, a symbol is selected on the second row. If the child's answer is correct, one on the third row is chosen. If the direction is correct, at least two symbols on the fourth row are selected, one with its arms pointing up or down, and the other with its arms pointing to the left or right. One must

FIGURE 4. *Method of Using the Occluder.*

glance at the child frequently to see that the occluder is kept in place, as well as to see that he semaphores correctly.

If the child reads two or more symbols on the fourth row, the vision is recorded as 20/20. If he

MEDICAL PROGRESS

PHYSIOLOGY*

HEBBEL E. HOFF, M.D.†

MONTREAL, CANADA

THE last days of 1944 will bring a centenary as significant to physiologists and to all those whose concern is with experimental medicine as it is to surgeons and obstetricians. On the morning of December 11, 1844, Horace Wells, a dentist of Hartford, Connecticut, noticed the insensitivity to pain produced by nitrous oxide gas administered to Samuel Cooley by C. Q. Colton at a private exhibition, which followed a public lecture and a demonstration of "laughing gas" held the night before. Acutely conscious of the problem of pain in dental operations, because of the multiple extractions necessitated by an improved dental plate that he and W. G. Morton had devised somewhat earlier, Wells at once foresaw the practical application of the phenomenon he had witnessed. Enlisting Colton's aid, he returned to his office, where he inhaled the gas himself, while a fellow dentist removed a tooth that had been bothering him. Wells's subsequent efforts to introduce nitrous oxide as an anesthetic agent failed, and it was not until thirty years had passed that Colton, ever mindful of what he had seen in Hartford, persuaded another dentist to give public trial to the method, this time successfully. Wells's discovery nevertheless retains stature in the history of anesthesia, not only in the matter of priority as the second in the series of Long, Wells and Morton, but because of the intimate background this work forms to that of Morton, which introduced anesthesia to the world. Although in surgery equal honors are shared by asepsis and anesthesia, the former plays a lesser role in physiology, particularly in acute experiments and in species whose resistance to wound infection surpasses that of man. Anesthesia is, in truth, the cornerstone of physiologic technic, and the development of experimental medicine has been fostered in no insignificant way by the discovery that is shortly to be celebrated.

NITROGEN BALANCE IN STATES OF DAMAGE

In the progress report on physiology for 1941,¹ significance was seen in reports stressing the importance of high-protein diets in circumstances likely to be complicated by liver damage. Since then the subject of high-protein diets has attained a position as one of the most prominent factors in the care of patients suffering from infections, fractures

or burns, and in fact from almost any condition that inflicts damage on the organism.

The protein requirement of everyday life has not lacked attention, and it is generally assumed that for the average adult a daily intake of 1 gm. of protein per kilogram of body weight² is adequate. This may be reduced to 0.5 to 0.7 gm. in the presence of a high intake of carbohydrate and fat,³ owing to their protein-sparing activity. During pregnancy the protein intake may be increased by a half, and during lactation it should be two and a half times the usual amount.² Infants require no less than 4 gm. of protein per kilogram of body weight, and even at six years of age 2 to 3 gm. must be supplied.⁴

The increased protein requirements in typhoid fever have been recognized since 1909, and the work of Whipple demonstrated the importance of increased protein intake for the regeneration of hemoglobin during recovery from anemias. Peters and Bulger⁵ called attention to the fallacy of restricting the intake of protein in the nephritic syndrome, and demonstrated that patients losing albumin through diseased kidneys were often seriously depleted of protein, and required as long as three months to restore their protein stores when placed on a more adequate diet.

The more recent developments in this field come from two sources: the recognition by surgeons of the importance of an adequate protein intake in promoting adequate wound healing and the discovery of important protein loss in the early days following trauma—the so-called "toxic protein loss." The first phase no doubt stems from the work of Clark⁶ in 1919 on the influence of diet on the healing of wounds. He noticed that in dogs fed a fat-rich and protein-poor diet a period of quiescence occurred on suture of an experimental incision, which postponed by six days the beginning of healing and eventual recovery. Healing began at once in dogs fed a high-protein diet, shortening the time for full recovery by six days. Revived by Ravdin and his collaborators,⁶ the work of Clark has been fully substantiated, and Koster and Kasman⁷ have shown that the average concentration of plasma proteins in 40 cases of wound disruption was significantly lower than it was in 40 control cases of well-healed wounds. Difficulties due to a low intake of protein appear to be most serious in patients suffering from gastrointestinal disorders requiring surgery. This is partly because these patients have voluntarily

*From the Department of Physiology, McGill University

†Professor of physiology, McGill University.

vision test, even though this is not required by law.*⁵ Such children often require glasses for near work only, and may even leave them in school. It is of historical interest that Dr. Henry Willard Williams, first ophthalmic surgeon to the Boston City Hospital, presented a paper to the railroad surgeons of America in Chicago shortly after the Civil War in which he suggested this as a disqualifying test for railroad employees.

Such a committee could encourage the inclusion of some simple color-perception test, especially for junior-high-school pupils, who might be planning a career in art, aviation, the Navy or the textile industry. A few pieces of colored yarn or a half-dozen colored pencils would suffice to detect the color blind. The best approach to this group might be made through the Department of Vocational Guidance.

This work can progress to the study of regressive reading habits, heterophoria and stereopsis and to

*The simplest test for this purpose is one of a battery of tests known as the Massachusetts test, developed by Oak and Sloane.⁵ It is accomplished by placing a pair of spectacles containing plus spheres (+1.50 or +2.00) before the eyes of a child who has 20/20 vision. If he can still read 20/20, his farsightedness may well cause symptoms, either ocular or systemic, and reference for an eye examination is advisable.

the gaining of other information that may be of importance in promoting normal educational progress. But before any of these are undertaken, the important thing is to find out whether every school child has normal vision. With this work well done we shall be better qualified to evaluate properly the new lighting fixtures, optical aids and ophthalmic correctional devices so highly publicized. In this way a goal may be reached that is worthy of the American medical and educational tradition.

I am indebted to Lieutenant Commander E. H. Danis (MC), U.S.N.R., for calling the most recent type of Naocluder to my attention.

520 Commonwealth Avenue

Drink-o give publi r in these experiments was supplied by ully. Well- n which the salt in sea water is chemically n the histo ted.

of priority experiments have covered the effects on the and Morⁿ of varying degrees of dehydration. Earlier ground th by Collier and Maddock³⁰ indicated that introduce signs of dehydration begin when about 6 surgery it of the body's weight in water is lost. If anesthesi lost without excessive sweating, sodium and ology, He accumulate in the extracellular fluid of the species w In dogs deprived of water and food, loss of that of n and chloride is reduced practically to zero of phys gh the failure of the kidneys to excrete these perimer ances.³¹ The burro, an animal acclimatized to signific vironment of great heat, is said to sweat almost be cele water, and even man guards against excessive NITR of salt by reducing the amount of this substance rolonged sweating.³¹ The net result of this In less is a growing hypertonicity of the extra-signifi lar fluids, including the plasma. Concentrations portatigh as 186 milliequiv. of sodium and 133 millil-likely v. of chloride per liter of serum have been the ad in the dehydrated dog.³² Positlosely associated with the hypertonicity of the care- extracellular fluid of the body is an extra excretion potassium — that is, one unassociated with nitro-³³ loss — in the urine.³³ This can only mean that tassium has moved out of the cell, along with cell

water, and that this process mitigates the loss of extracellular fluid. Renal activity is essential for the process, for in animals with ligation of the ureters the phenomenon does not occur. Apparently, loss of potassium in excess of that derived from breakdown of tissue takes place in a number of circumstances in which the volume of extracellular fluid is reduced or the fluid in this compartment is hypertonic. Among the first to note the phenomenon were Gamble, Ross and Tisdall,³⁴ who detected it in fasting diabetic children, and concluded that it indicates dehydration of intracellular fluid as well as extracellular water loss. In diarrheal disease in children, Butler, McKhann and Gamble³⁵ noted that intracellular water was lost in quantities greater than was extracellular water. Atchley, Loeb and their co-workers³⁶ noted an increased potassium excretion during glycosuria or acidosis in diabetics, indicating that intracellular fluid participates in the dehydration developing in this condition. Excess potassium loss occurred even when sodium chloride was added to the dietary of salt-deficient animals,³⁷ and when dogs were bled to an extent of 2.0 to 3.5 per cent of their body weight.³⁸ These authors commented:

We are accustomed to regard interstitial fluid as an extensive reservoir from which plasma losses can be readily replaced, its electrolyte composition being so nearly identical with that of the plasma. That water and the unsuitable electrolyte, potassium, should also be immediately withdrawn from tissue cells would not, on teleological grounds, be expected.

They found the potassium to have a concentration in the urine three times as great as that in cell water, indicating that cell water is retained in the plasma, whereas cell electrolytes, unsuitable for plasma construction, are excreted.

Ingestion or infusion of a variety of salts — sodium sulfate, ammonium chloride, urea and so forth — causes an extra excretion of potassium in the rabbit,³⁹ dog⁴⁰ and man.⁴¹ Wiley and Wiley⁴² followed the process somewhat more closely in a man.⁴² They found that a normal man can be dehydrated to an extent of about 1.5 per cent of his body weight without any great disturbance of salt balance, presumably because of the ability of the organism to concentrate its fluids to some extent. With more marked dehydration — to 5 per cent of body weight — there was an initial loss of sodium and chloride and a persisting loss of potassium, which indicated that, although extracellular fluid is probably the first to respond to water deprivation, there is also a loss of cellular water. When further loss of water was avoided, there was a continued loss of body potassium and a retention of sodium, denoting that a shift from cells to blood serum and interstitial fluids was taking place. When, finally, water was administered in amounts sufficient to restore the original water content of the body, sodium was lost and potassium was retained. The authors concluded that most of this water was thus retained

restricted their diet owing to the symptoms of their disease, and Riggs, Reinhold, Boles and Shore⁸ have recorded a somewhat lower average serum protein concentration in a group of ulcer patients (6.7 gm. per 100 cc.) than in a control group (7.2 gm. per 100 cc.). Since, as Taylor and others⁴ point out, the serum protein level is maintained at the expense of body protein and a deficit of 1 gm. of serum protein indicates on the average a depletion of 30 gm. of tissue protein,⁹ a moderate depletion of serum protein may indicate a substantial loss of protein from the body. In addition, surgeons have almost universally reduced the intake of patients undergoing surgery of the gastrointestinal tract. Intakes of 80 to 2200 calories a day are probably typical of this kind of treatment.⁹ Far from helping either the patient or the surgeon, this procedure, or the depletion of protein resulting from it, causes edema of the gastrointestinal tract, which impedes the surgeon, slows emptying time and promotes vomiting, thus delaying recovery.¹⁰⁻¹⁴ Since the total store of protein in an average adult body is around 2 kg., representing in the hydrated state as much as 11 kg., which if no other source of food were available would supply the basal caloric requirements of the body for only five days or thereabouts, it can be understood that starvation of a patient for five days to a week after operation may seriously deplete the available stores of body protein. A good part of these stores consists of muscle protein, which can hardly be considered as an inert material like fat. This depletion undoubtedly contributes largely to the asthenia seen in patients who have undergone major surgical intervention.

The second factor contributing to the deficit of protein in injury and illness appears to be a regular response to acute illness, whether it be the result of infection, trauma or burn. This toxic loss of nitrogen reaches a maximum on the fourth to the eighth day after the trauma,^{15, 16} and may entail in a ten-day period the loss of as much as 137 gm. of nitrogen, over 850 gm. of dry protein or as much as 4 kg. of body substance. There is a concomitant rise in temperature and a parallel increase in basal oxygen consumption. In trauma, burns and hemorrhagic shock, there is an increase in blood sugar,¹⁷ which according to some¹⁸ may be an unrelated phenomenon, but in the view of others¹⁹ it is certainly a part of the same mechanism. According to the latter, it represents the breakdown of tissue protein, either to supply glucose to meet the needs of the body for extra sugar in an emergency or to supply building blocks for repair in the damaged areas. However beneficial the immediate effects of an increase in blood sugar may be, its continuance can hardly fail to be harmful to the body. Whatever its function, its immediate stimulus may be the secretion of the gluconeogenic hormone of the adrenal cortex.¹⁹

ve outlines resembling the coast of Maine. Note the occurrence of the lesion at the lower end of the femur. In the lateral view you can see how the lesion is extending into the bone from without. There is another case showing exactly the same thing.

So far as I am concerned, this man had a neurofibroma. I shall, however, cover myself a little bit.

CLINICAL DIAGNOSIS

Benign giant-cell tumor of femur.

DR. ALBRIGHT'S DIAGNOSIS

Neurofibroma of femur.

ANATOMICAL DIAGNOSIS

Neurofibroma of femur.

FIGURE 1. *Anteroposterior and Lateral Roentgenograms of the Femur.*

The question arises, Why was there a periosteal change in the x-ray films? I think that he had a fracture and that the periosteal proliferation was due to that. I have seen this same kind of periosteal reaction in an eosinophilic granuloma, but that is a poor second choice. And any other diagnosis I can think of is equally poor.

A PHYSICIAN: What about malignant disease?

DR. ALBRIGHT: Do neurofibromas ever become malignant?

DR. JOSEPH AUB: Yes.

DR. CHARLES S. KUBIK: Have we ever had a case with sarcomatous degeneration?

DR. BENJAMIN CASTLEMAN: Yes.

DR. KUBIK: Von Recklinghausen's disease, with other tumors?

DR. CASTLEMAN: Yes; I remember at least one, and I believe we have had others.

PATHOLOGICAL DISCUSSION

DR. CASTLEMAN: Because of the cystic character of the lesion, this patient was operated on with a preoperative diagnosis of benign giant-cell tumor. At operation the surgeon made a window in the very thin cortex, the surface of which was extremely rough, and a large amount of yellowish, friable and, in places, semi-liquid material poured out. The surgeon removed all this material with a curet, leaving a thin shell of bone around a cavity that included both condyles and extended up the femur for about 6 cm. I saw the material at the time of operation and thought that it looked grossly like a benign giant-cell tumor. I did a frozen section and could not see any giant cells, but I did see some foam cells, which are often present in a giant-cell tumor. When the final sections came through, it proved to

CASE 30401

PRESENTATION OF CASE

A forty-five-year-old man, a funeral director, entered the hospital complaining of pain and swelling of the left knee.

Two years before admission the patient first noted minor pains in the left knee, which he attributed to arthritis. For six months prior to entry he noticed, while walking, that the left knee felt insecure. Five weeks prior to entry, while walking on the street, the knee suddenly gave way from under him. There was no pain, but swelling occurred for the first time. He consulted a physician, who made x-ray studies of the knee and told him that he had a "bone tumor." The leg was placed in a posterior mold from heel to groin. He remained entirely comfortable until admission to this hospital. There had been no chills or fever or any redness about the knee. He had had no pain in any other joint.

So far back as he could remember he had had multiple small nodules on the extensor surfaces of the arms and the anterolateral surfaces of the thigh and legs. These had not increased in size or number and had never been painful.

Physical examination showed a well-developed and well-nourished man in no acute discomfort. There were multiple firm, ovoid, freely movable, nontender, subcutaneous nodules on the dorsal surfaces of both forearms and of the left thigh. There was a tender swelling over the lower portion of the left femur. Most of the tenderness was over the medial parapatellar aspect of the condyle of the femur. Examination of the heart, lungs and abdomen was negative.

The blood pressure was 130 systolic, 82 diastolic. The temperature, pulse and respirations were normal.

The urine was normal. The blood showed a white-cell count of 10,300, with 76 per cent neutrophils, and a hemoglobin of 15.8 gm. per 100 cc.

A roentgenogram of the lower end of the left femur showed destruction of the normal bony structure with preservation of most of the cortex. The cortex was thin, and anteriorly and laterally appeared to be broken through, with an accompanying

periosteal reaction (Fig. 1). The joint surfaces were intact. There was no soft-tissue mass visible around the bones. Films of the spine showed that the left intervertebral foramen between the second and third cervical vertebrae was increased in size, and there were pressure defects involving the bodies of the second and third vertebrae in this area. Stereoscopic views showed flattening of the pedicles of the third cervical vertebra and probable, but not definite, slight enlargement of the intervertebral foramen. Films of the skull, arms and forearms were normal. A chest roentgenogram showed scarring in both apices, with calcification and fibrosis. There was scalloping of the inferior margins of several of the ribs, particularly the seventh on the left, but no definite soft-tissue masses were seen.

An operation was performed on the fifth hospital day.

DIFFERENTIAL DIAGNOSIS

DR. FULLER ALBRIGHT: The diagnosis depends on the x-ray films and is not too difficult, I believe. Let us look at the films.

DR. MILFORD SCHULZ: This is the film of the knee made some time before entry. Here are the films taken at the time of his visit to the hospital. Between these examinations he developed a little more periosteal reaction.

DR. ALBRIGHT: I may be "all wet," but if this is not neurofibromatosis I shall be greatly surprised. The patient had multiple subcutaneous nodules. He had evidence of multiple enlargement of the nerves, with definite enlargement of one cervical foramen. He had a lesion in a very characteristic location for a neurofibroma, namely, the lower end of the femur.

The bone lesion in neurofibromatosis is not strictly a bone lesion but is an encroachment of a tumor of the nerve on the bone. The lesion is apt to occur where nerves enter the bone. In the anteroposterior view it often looks like a cyst; and in the lateral view one can often see — but not in this case — that the cyst-like appearance is due to a lesion on the outside extending into the bone. The most frequent site of the bone lesions in neurofibromatosis is the lower end of the femur. I am so confident that this is a case of neurofibromatosis that I brought along a few slides of some other cases for comparison. I will not consider any other diagnosis.

Here is a case of neurofibromatosis showing brown spots on the skin and subcutaneous nodules. The brown spots are characteristic. They have smooth edges like the coast of California, which are distinctly different from those in the disease that I have recently been interested in, osteitis fibrosa disseminata or what is perhaps a better name "polyostotic fibrous dysplasia," where the brown skin lesions

*On leave of absence.

matous. We reviewed the slides of the original tumor, of which we had made a large number,

FIGURE 4. Photomicrograph of the Recurrent Tumor.

but could find not the slightest evidence of malignancy.

CASE 30402

PRESENTATION OF CASE

A six-week-old girl was admitted to the hospital because of "blue spells."

The infant was one of twins, delivered after an easy, normal labor, and weighed slightly over 4 pounds at birth. At the age of two weeks it was noted that she had difficulty getting her breath while feeding. This symptom persisted. Two days before entry she was taken to a pediatrician, who found an enlarged heart and liver. On the day of admission she had three episodes of cyanosis, the first being the severest and lasting forty minutes.

Physical examination showed a well-developed, fairly well-nourished, slightly dusky infant. The lungs were clear. The heart was markedly enlarged to the left, extending 2 cm. outside the midclavicular line and 3 cm. to the right of the sternum. No murmurs were heard. The sounds were distant. The liver was palpable 3 cm. below the right costal margin.

The temperature was 98°F., the pulse 120, and the respirations 60 to 80.

Examination of the blood showed a white-cell count of 10,640, with 46 per cent neutrophils, 8 per cent large and 44 per cent small lymphocytes and 20 per cent eosinophils.

X-ray examination of the chest showed a definitely enlarged heart without a characteristic configuration. An electrocardiogram revealed a sinus tachycardia, with a rate of 200, slight left-axis deviation, deep S₁, S₂ and S₃ and late inversion of T₁ and T₂; T₃ was upright. A repeat electro-

cardiogram seven days later showed no appreciable change.

The child was placed in an oxygen tent. The respirations fell to about 55 and she had no "cyanotic spells," but whenever she was out of the tent for half an hour to an hour the color became poor. Otherwise her condition remained unchanged until the eighth hospital day, when she started to cough and became cyanotic while being fed. She was put back into the oxygen tent but died five minutes later.

DIFFERENTIAL DIAGNOSIS

DR. CONGER WILLIAMS: The electrocardiogram is obviously abnormal. It is more usual at this age to see right-axis deviation than left, although the latter may be present. Of course the T wave inversion in Leads 1 and 2 is abnormal. Other than that there is nothing about the pattern that gives any specific help. A heart rate of 200 does not suggest paroxysmal tachycardia in an infant. Sinus tachycardia as a direct result of heart disease is likelier.

In discussing the differential diagnosis there are three groups of congenital conditions — and I think it is obvious that this child had a congenital condition — that should be considered. The first group includes the mechanical defects of the great vessels, such as transposition of the trunks, defects of the valves, for example, aortic stenosis and pulmonary stenosis, and septal defects — auricular and ventricular. In order to make such a diagnosis one must have more evidence than I have here. No characteristic murmurs were heard. In a great many congenital defects an electrocardiogram is helpful in that high voltage and right-axis deviation are present, this being particularly true in infants who are deeply cyanotic. In this case, however, the electrocardiogram gives no assistance. One thing that helps a little in narrowing the field down is the degree of cyanosis. The fact that it was moderate and not constant rules out the congenital malformations characterized by marked cyanosis, transposition of the great trunks with septal defect, cor biloculare with persistent truncus and so forth. Those conditions are usually compatible with life for only a few days or weeks.

Another condition that must be considered is the tetralogy of Fallot, which usually is accompanied by more cyanosis than was noted here. Cyanosis, however, is not always present before the age of two. I believe that that diagnosis can be ruled out by the absence of characteristic murmurs and of evidence of right-axis deviation in the electrocardiogram. More frequent defects, such as an auricular septal defect, ventricular septal defect and patent ductus arteriosus, do not usually produce death at this age unless they are extremely large, and two of these conditions are associated with

be a neurofibroma with areas of degeneration that contained a large number of foam cells (Fig 2).

DR. LAURENCE L. ROBBINS: The lesions of neurofibroma of bone that we see usually have a charac-

bone, although it may have started in a periosteal nerve and, instead of extending outward, extended inward.

ADDENDUM

DR. CASTLEMAN: The patient was well and free from symptoms for the following ten months, when he noticed enlargement of the knee. A roentgenogram (Fig. 3) showed an area of destruction just above the condyle that was not present in previous films. It also showed considerable periosteal proliferation extending up the shaft, with similar changes about the cavity filled with bone chips. A chest plate was normal. Since it was thought that the tumor had recurred and had become malignant, a mid-thigh amputation was performed.

The tumor involved the lowermost 10 cm of the femur and had extended into the surrounding tissues, especially the popliteal and suprapatellar regions, to form large soft-tissue tumor masses. There was no involvement of the tibia, although the articular cartilage was eroded. Microscopically the change from the original tumor was striking. The cells were large and atypical, and mitoses were numerous (Fig. 4). This is an example, therefore, of a case of

FIGURE 2 Photomicrograph of the Tumor

teristic appearance. They erode the periosteal margins of the bone, producing an indentation of

FIGURE 3 Anteroposterior and Lateral Roentgenograms of the Femur
Note the large, soft-tissue masses. The bone lesion is filled with bone chips. There is an area of destruction on the medial margin of the lower shaft and condyle.

the cortex. In this case, from the appearance of the x-ray, the lesion seems to have arisen within the

generalized neurofibromatosis in which one of the benign neurofibromas involving bone became sar-

ght. The valves were normal. There was a slightly patent foramen ovale, which was probably of no significance. The aorta, just beyond the arch and at the level of the ductus arteriosus, which admitted a 2-mm. probe, was slightly narrow, so that I think that we can make a diagnosis of slight coarctation of the aorta. The liver was normal in size for a child of this age, weighing 125 gm., and all the other organs were normal.

Microscopic examination of the heart muscle proved that this was a case of glycogen-storage (von Gierke's) disease. The myocardial fibers were

filled with glycogen, and even after fixation in formalin, in which ordinarily the granules are dissolved out, we were able to find the deposits of glycogen. There were relatively few granules in the liver. This falls in with the type of disease that is confined almost wholly to the heart, without involvement of the liver or kidneys.

DR. WILLIAMS: Was a urine examination reported? It is not given in the abstract, and it might have been helpful in the diagnosis if it had shown persistent acetonuria.

DR. CASTLEMAN: No examination is recorded.

characteristic murmurs, which this patient did not have.

One anomaly falling into this group that is consistent with the findings is abnormal origin of a coronary artery. Cases have been reported in which one of the coronary arteries, usually the left, rises from the pulmonary artery. In other cases there is only one coronary artery, which arises from the aorta. Ten years ago Dr. Paul D. White reported a case of an anomalous coronary in a boy three and a half months old who died following a series of attacks of cyanosis, sweating and dyspnea.* The child's electrocardiogram was grossly abnormal, with the most important changes in Leads 1 and 2, as they were here. The findings of cardiac enlargement without murmurs and a rather characteristic electrocardiogram are entirely in keeping with that diagnosis.

The second group of congenital disorders is that characterized by changes in the heart muscle itself. The most frequent is congenital idiopathic hypertrophy. Obviously the name is unsatisfactory. The group so designated is getting smaller all the time as more specific causes for hypertrophy are found. Many cases remain, however, in which the only finding at death is that of a large heart uncomplicated by any other anatomical finding. The findings in this case — the early death, the paroxysms of cyanosis and so forth — are entirely in keeping with this diagnosis. In the same group one must also consider von Gierke's or glycogen-storage disease, in which there is a disorder of glycogen metabolism. The most characteristic finding is that of hepatic enlargement. The heart may or may not be enlarged, but in some cases the heart enlarges proportionately more than the liver. Usually this is a chronic disease and patients live for years, but early deaths have been reported. I was interested in the description of the liver, which was said to have been definitely enlarged. That may mean something. The spleen was not enlarged. The absence of splenomegaly is another characteristic of glycogen-storage disease.

The third group to be considered is that characterized by lesions in the circulatory system outside the heart, especially in the lungs. A number of cases have been reported in these conferences — one of which I misdiagnosed — in which the chief lesion was a developmental defect of the pulmonary circulation. It usually consists of a lack of differentiation of the small radicles and capillaries into their usual subgroups which results, ordinarily, in a primitive, narrow circulation that obstructs the pulmonary flow. Such cases have been reported with findings similar to these. The only thing lacking in this case is an electrocardiographic pattern showing evidence of right-axis deviation.

*Bland, E. F., White, P. D., and Garland, J. Congenital anomalies of coronary arteries: report of unusual case associated with cardiac hypertrophy. *Am. Heart J.* 8:787-801, 1933.

In reaching a final diagnosis, there is one differential point of the greatest importance that cannot be answered with certainty. Was the enlarged liver the result of heart failure or of intrinsic liver disease (glycogen-storage disease)? A definite statement about the neck vessels might have answered that question, because when the liver enlarges as a result of heart failure, the neck veins almost invariably either are distended or show characteristic pulsation. Not having that statement I am forced to make a differential diagnosis that includes the three conditions, and I shall name them in the order of probability: idiopathic cardiac hypertrophy, glycogen-storage disease and an anomalous coronary artery. I cannot make a diagnosis of septal defect, valvular defect or an anomaly of the great vessels.

DR. T. DUCKETT JONES: I should like to ask Dr. Williams whether he thinks that, in general, the findings in the neck veins are as significant in children as they are in adults.

DR. WILLIAMS: Venous pulsation probably is. One does not often observe distended neck veins except in cases with a high degree of obstruction to the venous circuit. I do not see a great many infants, but my impression is that the neck veins show abnormal pulsations in the presence of increased venous pressure, even in infants.

DR. JONES: I have been impressed with the facts that in right-sided failure in young children the liver is easily palpable, and that neck signs, which might lead to an early diagnosis, are usually absent.

CLINICAL DIAGNOSIS

Congenital heart disease (idiopathic hypertrophy).

DR. WILLIAMS'S DIAGNOSIS

Congenital idiopathic cardiac hypertrophy?
Glycogen-storage (von Gierke's) disease?
Anomalous coronary artery?

ANATOMICAL DIAGNOSES

Glycogen-storage (von Gierke's) disease of heart.
Cardiac hypertrophy.
Coarctation of aorta, slight.

PATHOLOGICAL DISCUSSION

DR. BENJAMIN CASTLEMAN: Dr. White saw this patient in consultation; he thought that the changes were consistent with a congenital anomaly of the coronary arteries and referred to the patient whom he had seen before.

The autopsy showed an enlarged heart, weighing 50 gm., which is about two and a half times the normal weight for a child of this age. The enlargement was uniform throughout the chambers, but slightly more prominent on the left than on the

On the basis of these studies and the reports of a number of clinicians, the Russian workers urged the use of this antireticular cytotoxic serum for the treatment of a wide variety of conditions, which include all types of infectious disease, particular attention being made of typhus fever, puerperal and necrologic sepsis, rheumatic fever, tonsillitis, unresolved pneumonia, lung abscess and infectious diseases of the nervous system. They also believed that their clinical observations had established the therapeutic efficacy of this serum in war injuries of various sorts, including fractures, frostbites, second-degree and third-degree burns, early and late purulent infections of the cavities and tissues, and infected lesions of the eye. It was particularly effective in slowly healing infected wounds. They even felt justified in recommending its use in the treatment of neuritis, meningoencephalitis, disseminated sclerosis, senile and presenile psychoses, and schizophrenia. Some "encouraging results" were also obtained in the treatment of peptic ulcer, eczema and other "trophic" disturbances. Although not included in the list of indications, it is apparent that at least the senior author also thought that this substance might give favorable results in the prevention and treatment of cancer and senility. In fact, it was this author's interest in the latter that was largely responsible for the studies that led to the development of the serum.

These results may seem rather fantastic to "hard-boiled" American scientists who are accustomed to have extensive and thoroughly documented evidence presented for any new discovery of such far-reaching significance before they consider it even plausible. Before taking it seriously, they would undoubtedly like to see this work repeated by many independent workers under carefully controlled conditions. Unfortunately, the details of the Russian observations are not readily accessible in a form in which they can be properly evaluated by workers in this country. Until they are, one must consider these findings with an open mind.

At the time of the publication of these reports, the editor of the *American Review of Soviet Medicine* was apparently quite enthusiastic about the possibilities offered by this serum. Indeed, he was moved to write a note in preface to the issue, which

ended in an appeal to expedite further studies with this serum. Clinical investigators in this country, who are not always easy to convince and who are usually quite wary of accepting such cure-alls, will undoubtedly prefer to await more detailed evidence of the efficacy of this agent before embarking on any clinical trials of their own. If one may judge from the tone of an editorial note printed in the following issue of the *American Review of Soviet Medicine*, it is evident that the former note was not enthusiastically received.

MASSACHUSETTS MEDICAL SOCIETY

EXECUTIVE COMMITTEE OF THE COUNCIL

On August 30, 1944, the Executive Committee of the Council, on the recommendation of the Committee on Membership and representatives from the supervising censors, took the following actions:

Allowed the following named fellows, applying for retirement and with all dues paid and in good standing, to retire under the provisions of Chapter I, Section 5, of the by-laws, such retirement to be effective as of January 1, 1944:

Cavanaugh, Thomas E. (Hampden), 293 Bridge Street, Springfield.
Dexter, Fred F. (Hampden), 151 Maple Street, Springfield.
Gorham, George H. (Norfolk), 91 Crest Avenue, Chelsea.
Johnson, Erik St. J. (Middlesex South), 8 Follen Street, Cambridge.
Ruble, Wells A. (Nonresident), 1929 East Glenoaks Boulevard, Glendale, California.

Allowed the following named fellows, applying for retirement, to retire with remission of dues owed the Society under the provisions of Chapter I, Section 5, of the by-laws, such retirement to be effective as of January 1, 1944:

Avedisyan, A. D. (Middlesex South), 164 Huntington Avenue, Boston.
Barton, John A. (Worcester North), 61 Fox Street, Fitchburg.
Ford, J. Francis (Norfolk), 8 Walter Street, Roslindale.
Hunt, Daniel L. (Suffolk), Hotel Vendome, Boston.
Nightingale, James (Worcester), 14 Puritan Avenue, Worcester.
Sargent, Oscar F. L. (Nonresident), 45 North Main Street, Farmington, New Hampshire.
Stevens, Harry L. (Bristol South), 133 Kempton Street, New Bedford.

Reinstated the following named physician, under the provisions of Chapter I, Section 10, of the by-laws, who had been deprived of fellowship for the nonpayment of dues, provided his arrears in dues at the time he was dropped plus the dues for 1944 be paid to the treasurer of the Society:

Wainshel, P. W. (Essex South), 92 South Common Street, Lynn.

THE JOURNAL does not hold itself responsible for statements made by any contributor.

COMMUNICATIONS should be addressed to the *New England Journal of Medicine*, 8 Fenway, Boston 15, Massachusetts.

THE BLUE TRIANGLE

It will be readily appreciated that there will always be a large number of people who, for one reason or another, have not covered their catastrophic medical costs by prepayment insurance placed with commercial companies or with the Blue Shield or the Blue Cross, or both.

For about two years committees of the Massachusetts Medical Society and of the Massachusetts Bankers Association have been jointly considering a dignified postpayment plan for medical costs. The Association has gone into this plan extremely thoroughly, consulting proper authorities regarding the strategies, the legal aspects and the technical machinery of putting such a plan into effect.

The Massachusetts Medical Society authorized its committee to participate in the planning and to initiate the program after the plans had been completed.

The groundwork has been accomplished. The plan — the Blue Triangle — is ready and will soon be put into operation. All members of the Massachusetts Medical Society will receive detailed information through their local banks. Each member should become thoroughly familiar with the opportunities provided by the plan and should make them known to those of his patients who might benefit thereby.

ANTIRETICULAR CYTOTOXIC SERUM

CONSIDERABLE though brief interest was manifested in this country recently in a serum developed in Soviet Russia that was reported to have remarkable curative and healing properties. Some of the details concerning this remarkable discovery were presented at a special conference of clinicians and biologists that took place in Ufa in July, 1942. A brief report of the experimental and theoretical background and of some of the clinical applications of this serum is given in a series of papers published in the December, 1943, issue of the *American Review of Soviet Medicine*.

Over a number of years a group of Russian investigators, under the leadership of Professor A. A. Bogomolets, have conducted an extensive series of investigations on the effects of cytotoxic serums. Their results have led them to believe that small doses of antireticular cytotoxic serum stimulate mesenchymal cells, whereas larger doses block these cells. To prepare organotoxic immunizing serums for any animal, they use desiccated cells from another type of animal. Using cells of the spleen and marrow, they obtain serum that is cytotoxic to mesenchymal cells and that Doctor Bogomolets calls "antireticular." For use in human beings, the antireticular cytotoxic serum is prepared by immunizing animals with an antigen derived from the spleen and marrow of human cadavers. These organs must be obtained not later than six to ten hours after death in cases in which there has been no evidence of infectious disease.

DEATHS

BERMAN — Saul Berman, M.D., of Chestnut Hill
Newton, died September 18. He was in his forty-ninth year.
Dr. Berman received his degree from Harvard Medical
School in 1920. He was formerly resident physician at the
Boston Lying-in Hospital and was the founder of the Fer-
ity Clinic and Laboratory at the Beth Israel Hospital. He
was a member of the Boston Obstetrical Society.
His widow and three sons survive.

GAGNON — Alphonse P. Gagnon, M.D., of Taunton
died August 2. He was in his fifty-third year.

Dr. Gagnon received his degree from Tufts College Medical
School in 1921. He was a member of the American Medical
Association and the New England Society of Obstetrics
and Gynecology.

His widow, a son and a daughter survive.

SPARROW — Charles A. Sparrow, M.D., of Worcester
died September 20. He was in his sixty-first year.

Dr. Sparrow was born in Marion and graduated from
Amherst College in 1906, receiving his degree from Harvard
Medical School in 1909. He was appointed to the staff of
Memorial Hospital in 1916 and in 1925 became head of the
Pediatric Clinic there. He was an associate editor of the
Worcester Medical News, a publication of the Worcester
District Medical Society, as well as a past president of the
society and a councilor of the Massachusetts Medical Society.
He was a member of the American Academy of Pediatrics
and of the New England Pediatric Society.

His widow, a son, a daughter and a sister survive.

MASSACHUSETTS DEPARTMENT OF PUBLIC HEALTH

COMMUNICABLE DISEASES IN MASSACHUSETTS FOR AUGUST, 1944

Typhoid fever	7	3	10
Undulant fever	5	3	4
Whooping cough	261	286	508

*Made reportable in December, 1943.

†Pfeiffer-bac

COMMENT

Interest in the communicable disease situation centers this month on anterior poliomyelitis, both because of the seasonal increase in cases and because of outbreaks in certain other states. At present, the number of cases in Massachusetts is far below that of epidemic years, although greatly in excess of the seven-year median.

Salmonella infections were at nearly double the seven-year median for August. These cases, however, were widely scattered about the state.

GEOGRAPHICAL DISTRIBUTION OF CERTAIN DISEASES

Anterior poliomyelitis was reported from: Adams, 1; Agawam, 1; Athol, 1; Barre, 1; Belchertown, 1; Boston, 5; Cambridge, 1; Chelsea, 1; Chicopee, 4; Dalton, 5; Deerfield, 4; Fall River, 2; Gloucester, 1; Great Barrington, 1; Groveland, 1; Haverhill, 5; Holyoke, 5; Lenox, 1; Ludlow, 1; Mansfield, 1; Marblehead, 1; Mattapoisett, 1; Natick, 1; Northampton, 2; Northborough, 1; Palmer, 2; Pittsfield, 21; Quincy, 2; Reading, 1; Revere, 1; Richmond, 1; Rockport, 1; Sandwich, 1; Sharon, 1; Southbridge, 1; Springfield, 39; Stockbridge, 2; Waltham, 1; Watertown, 1; West Springfield, 5; Westfield, 1; Whitman, 2; Wilbraham, 1; Williamsburg, 1; Williamstown, 1; Winchester, 1; Worcester, 1; total, 137.

Diphtheria was reported from: Boston, 3; Lowell, 1; Medford, 1; New Bedford, 1; total, 6.

Dysentery, bacillary, was reported from: Boston, 2; Lawrence, 1; Malden, 1; Milton, 1; Salem, 4; Worcester, 1; Wrentham, 8; total, 18.

Encephalitis, infectious, was reported from: Braintree, 1; total, 1.

Malaria was reported from: Boston, 4; Cambridge, 1; Camp Edwards, 15; Cushing General Hospital, 25; Lawrence, 1; Merrimac, 1; Somerville, 1; Springfield, 1; Weymouth, 1; Woburn, 1; total, 49.

Meningitis, meningococcal, was reported from: Agawam, 1; Beverly, 2; Boston, 14; Bourne, 1; Brockton, 2; Chicopee, 1; Dartmouth, 1; Gardner, 1; Lynn, 2; Somerville, 1; Springfield, 1; Sutton, 1; Swampscott, 1; Watertown, 1; Westfield, 1; West Bridgewater, 1; West Springfield, 1; Worcester, 1; total, 34.

Meningitis, Pfeiffer-bacillus, was reported from: Boston, 1; Cheshire, 1; Hampden, 1; total, 3.

CORRESPONDENCE

ALKALINIZATION DURING SULFONAMIDE THERAPY

To the Editor: I was both surprised and pleased to read the editorial "Alkalinization During Sulfonamide Therapy," which appeared in the September 14 issue of the *Journal*.

The author of this excellent editorial, I believe, is correct in pointing out that the key problem to be solved, before the use of potassium bicarbonate is given widespread acceptance, is not its rationale, for that is obvious, but rather the toxicity of potassium bicarbonate when given in the large doses necessary to achieve adequate urinary alkalinization (18 to 22 gm. on the first day and 12 to 15 gm. on succeeding days). We have not seen any toxic effects either in the cases reported in our paper or since then, but it is true that our

experience has been relatively small. From our review of the literature it seemed that potassium retention was only seen in really terminal uremia; the other situation under which potassium toxicity might be expected — untreated Addison's disease coexistent with congestive heart failure — is a metabolic paradox and rare enough to be considered a medical curiosity. It must be admitted, however, that this point of view is not shared by all; thus, Dr. Paul D. White in the 1944 edition of his book *Heart Disease* states, "Calcium (and potassium) salts in high dosage should not be administered to digitalized patients because of the hazard of serious toxic effects on the cardiac mechanism."

Although further demonstration of the harmlessness of potassium salts is desirable, I do not believe that the suggestion advanced by the author of the editorial to avoid possible toxicity is practicable. He suggests the use of smaller doses (5 to 10 gm. daily) of potassium bicarbonate; but, unfortunately, although this might eliminate the possibility of toxicity, it would probably also abolish the beneficial therapeutic effect. The reason for this is to be found in the solubility curves of sulfadiazine and acetyl-sulfadiazine, which only begin to rise rapidly as the alkalinity of the urine approaches pH 7.4. I am afraid that 5 to 10 gm. daily would not often serve to render the urine alkaline enough to achieve the desired effect.

Although we believe that our dosage schedule is not likely to cause toxicity, I should like to suggest that instead of using smaller dosages of potassium bicarbonate alone, those who fear potassium bicarbonate toxicity use a mixture of potassium bicarbonate and sodium bicarbonate. If 10 gm. of potassium bicarbonate and 4 gm. of sodium bicarbonate are given daily, one would be within the generally accepted limits of safe potassium dosage and would also be able to achieve satisfactory alkalinization without giving more sodium than is contained in the ordinary hospital salt-poor diet. This is, of course, only a makeshift at best and should be abandoned if the concept of the low toxicity of potassium salts becomes established.

A COMMUNITY BLOOD BANK

To the Editor: The editorial in the August 17 issue of the *Journal* pertaining to "Red-Cell Residues" is most excellent, commendable and timely. In the concluding sentences of the last paragraph, it reads: "One might think of each community with a blood-donor service prepared to supply whole blood, plasma, albumin, specific globulin fractions and erythrocyte suspensions. The proper use of such a service would require the co-operation of the physicians within the community, but the therapeutic possibilities are manifold."

May I call to your attention the fact that the Worcester District Medical Society has already established the type of service that the editorial portrays as a pious hope for the future. The Worcester blood bank, officially named the Worcester District Community Center for Aiding Transfusions, Incorporated, is sponsored by the Worcester District Medical Society and began its service to this community on October 12, 1942. It has given whole blood, plasma, erythrocyte suspensions and erythrocyte packs to any physician or hospital for the asking. In addition, we are serving the Lovell General Hospital at Fort Devens.

The cost of preparing this material is one of the lowest in the country, volunteer workers numbering over two hundred and only four full-time paid workers helping to keep the costs down. The expense of this service is supported in part by the patients receiving the material and in part by the Community Chest of Worcester.

This program is actual proof that a community without governmental help can successfully offer inexpensive community service. Furthermore, it can be said with emphasis that no one in the Worcester District has suffered from the lack of whole blood or blood components since this blood bank began its operations.

We believe that it is worth while to call this matter to your attention so that physicians in other communities can study the possibilities of community service without governmental dole.

BOOK REVIEWS

Roentgenographic Technique: A manual for physicians, students and technicians. By Darmon A. Rhinehart, M.D. 8°, cloth, 471 pp., with 201 illustrations. Philadelphia: Lea and Febiger, 1943. \$5.50.

A careful reading of this book indicates, in the opinion of the reviewer, that the technic proposed by this writer is the one that was in use a decade ago. It gives practically no information to the radiologist or technician in a large hospital for special work referable to the skull, such as encephalography and ventriculography, which are frequently employed.

Nervousness, Indigestion, and Pain. By Walter C. Alvarez, M.D. 8°, cloth, 488 pp. New York: Paul B. Hoeber, Incorporated, 1943. \$5.00.

The author, primarily a gastroenterologist, has long been interested in the nervous manifestations of diseases, particularly the resulting dysfunctions in the gastrointestinal tract. The book is the result of his long experience and is a personal report on what he has seen and recorded. He is thus in a position to evaluate many puzzling problems regarding one of the most complicated types of illness facing the general practitioner.

The book is full of sound advice, particular emphasis being placed on the diagnosis of disease from a complete history and physical examination from extensive laboratory data. The problems of constitutional inadequacy, nervous breakdowns and the menopause as well as many other topics, are handled with great skill. In reading the book one feels as though the author and his patient were in the same room and one was actually attending as an observer. The reviewer knows of no other book that so distinctively gives this impression. No one can read this book without being a better physician, and in it will be found the answer to many problems that have long been a trying annoyance to many practitioners. The various subheadings of the chapters give the tone of the book: "We, physicians, are giving our patients the impression that we diagnose only from laboratory reports"; "It is hard to take a good history without revealing one's knowledge as to the diagnosis"; "It is good to be somewhat neurotic"; "Nothing could be found at operation"; "The qualities desirable in the physician"; "Dilemmas that result from lying"; "Abdominal hallucinations"; "The woman who revels in medical treatment"; "The schoolteacher who tries every summer to get a master's degree"; and "What is the patient to do?"

This book is highly recommended.

Lincoln-Douglas: The weather as destiny. By William F. Petersen, M.D. 8°, cloth, 211 pp., with 16 illustrations. Springfield, Illinois: Charles C Thomas, 1943. \$3.00.

The author has long been interested in the effects of cosmic disturbances on disease. He has written a number of books on the weather and its relation to epidemics and even to individual disease. In this volume he contrasts the environments under which Lincoln and Douglas were raised and developed. Their backgrounds were essentially dissimilar, Douglas being raised in Vermont in a prosperous family, the mother being in excellent health, and the other born under depressed circumstances in a log cabin, his mother being ill and probably suffering from tuberculosis. The body build of the two men was also distinctly in contrast, Douglas was short, rotund, broadchested, with square shoulders, small hands and feet, and of a buoyant, energetic, bustling personality; Lincoln, on the other hand, was excessively tall, stoop-shouldered, gaunt and awkward, with a shrill, squeaking voice. With these data the author investigates the weather conditions during the life of the individuals and attempts to correlate the influence that these had on the career of the two men.

The theory seems strained to meet requirements, and the book is not entirely convincing. The volume, however, is of interest to the medical profession for it deals with a topic much in current discussion. How much stress should be put upon weather as an effective agent in individual destiny is, to most scientists, an unanswered problem. The author believes that it plays an important role, even an outstanding one.

MEDICAL CONFERENCE PROGRAM

Friday, October 6 — War Neuroses and Their Treatment in the Army. Major Jackson Thomas, U.S.A.

Wednesday, October 11 — Headaches Due to Ocular Disorders. Dr. Joseph J. Skirball.

Friday, October 13 — Deep Burns and Prophylactic Penicillin. Dr. Oliver Cope.

Wednesday, October 18 — Problems in Rhinology. Dr. Daniel Miller.

Friday, October 20 — Precordial Electrocardiography. Dr. Conger Williams.

Wednesday, October 25 — Pyuria in Children. Dr. James Marvin Baty.

Friday, October 27 — The Diagnostic Significance of Change in the Appearance of the Tongue. Dr. H. J. Jeghers.

On Tuesday and Thursday mornings Dr. S. J. Thannhauser will give medical clinics on hospital cases.

On Saturday mornings clinics will be given by Dr. William Dameshek.

NEW ENGLAND DERMATOLOGICAL
SOCIETY

Because of the holiday on October 12, the next regular meeting of the New England Dermatological Society will be held in the Skin Out Patient Department of the Massachusetts General Hospital on Wednesday, October 18, at 2 p. m.

NEW ENGLAND OTO-LARYNGOLOGICAL
SOCIETY

The regular fall meeting of the New England Oto-Laryngological Society will be held at the Massachusetts Eye and Ear Infirmary on Wednesday, November 15.

METROPOLITAN STATE HOSPITAL

The tenth Postgraduate Seminar in Neurology and Psychiatry will begin Wednesday, October 11, at the Metropolitan State Hospital, 475 Trapelo Road, Waltham. The program consists of fifty-four lectures and demonstrations in anatomy, applied physiology, pathology and roentgenology of the nervous system, clinical neurology and psychiatry. The lectures will be held every Wednesday from October 11 through December 13 and from January 3 through April 25, from 6 to 10 p. m. The seminar is open to all graduate physicians. Those interested are requested to register October 11 at 5:30 p. m. at the Metropolitan State Hospital.

TREATMENT OF MENINGOCOCCAL MENINGITIS WITH PENICILLIN*

MANSON MEADS, M.D.,† H. WILLIAM HARRIS, M.D.,‡ BERNARDO A. SAMPER, M.D.,§
AND MAXWELL FINLAND, M.D.¶

WITH THE TECHNICAL ASSISTANCE OF CLARE WILCOX

BOSTON

IN SOME of his early studies on penicillin, Fleming¹ reported that meningococci and gonococci are among the bacteria that are highly sensitive to penicillin in vitro and that they rank with staphylococci in this respect. This observation has been confirmed by others,²⁻⁴ but few strains were tested in each instance. Dawson and his co-workers⁵ showed, in addition, that penicillin is effective against experimental Group I meningococcal infection in mice. A total dose of 1800 Oxford units given subcutaneously in sesame oil a half, eighteen and twenty-four hours after intraperitoneal injection of organisms afforded complete protection against 10^{-5} and 10^{-6} dilutions of meningococci, and partial protection against 10^{-3} and 10^{-4} dilutions. These amounts of each of two cultures tested were fatal to control mice in twenty-four hours.

Clinical applications of these findings, as they concern the gonococcus, have been many,⁶⁻¹² but they have been chiefly confined to the treatment of sulfonamide-resistant gonorrhea, which almost invariably responds to penicillin in adequate doses. On the other hand, because of the good results obtained with sulfonamides, extremely few cases of meningococcal infections treated with penicillin have been reported. Keefer's¹³ series included 5 cases with 1 death. In the fatal case and one other the patient received only parenteral and no intrathecal therapy. Dawson and Hobby¹⁴ reported 2 cases of

meningitis; in one, both intrathecal and intramuscular penicillin were given after the patient developed anuria as a result of sulfonamide therapy; in the other, the patient, a seventeen-month-old baby, was given only intramuscular penicillin. The former recovered, and the authors believed that recovery was attributable to the penicillin. The latter made an unsatisfactory response to the penicillin and subsequently responded to antimeningococcus serum and sulfonamide therapy. Both groups of workers concluded that intrathecal as well as parenteral therapy with penicillin is probably necessary to obtain good results. Lyons¹⁵ reported the case of a successfully treated patient with meningococcemia without meningitis who had presumably relapsed after sulfonamide therapy. The War Department⁸ recommends penicillin therapy for meningococcal infections only if sulfadiazine cannot be given or if there is a failure to respond to that drug in forty-eight hours. For fulminating cases with bacteremia, collapse and purpura, it is recommended that both penicillin and sulfadiazine be given at the earliest practicable time.

In this paper are presented 9 cases of meningococcal meningitis, including 5 with meningococcemia, that were treated with the calcium salt of penicillin intrathecally and intramuscularly. The reason for presenting such a small series of cases in some detail will become evident from the character of the clinical response that was obtained.

CASES AND METHODS OF STUDY

The cases studied were unselected typical ones of meningococcal meningitis admitted to the Boston City Hospital during April, 1944. The ages ranged from fourteen to fifty-eight years. Seven patients were acutely ill and irrational, 1 was acutely ill and rational, and 1 was only moderately ill when first seen. The duration of the acute illness before entry ranged from one to seven days, averaging about three days. Two of the patients were alcoholic

*From the Medical Laboratory, Second and Fourth City Hospital, and the Department of Medicine.

†The penicillin used in this study was provided by the Office of Scientific Research and Development from supplies assigned by the Committee on Medical Research for clinical investigations recommended by the Committee on Chemotherapeutic and Other Agents of the National Research Council.

addicts, and 4 gave histories of their illness as starting with an acute upper respiratory infection. Blood for sulfonamide determination was taken routinely on admission to ascertain whether therapy with these drugs had been given before entry. No sulfonamide was found except in Case 9, in which the blood level was 2.4 mg. per 100 cc., calculated as free sulfadiazine. It was later learned that this patient had received an oral dose a few hours before entry. Lumbar punctures were done on admission and at twelve-hour to twenty-four-hour intervals, as will be indicated later. Cell counts, smears and cultures of the sediment and chemical studies of the cerebrospinal fluid were carried out routinely. Blood and throat cultures were made on admission and, in some cases, were repeated once or twice daily until they were negative.

Cultures of the spinal-fluid sediment obtained by high-speed centrifugation were made on the surface of 10 per cent horse-blood-agar plates and also in beef infusion broth containing 1 per cent horse blood. Incubation was carried out at 37.5°C. in a candle jar. The time elapsing between lumbar tap and culture was kept as short as possible in order to minimize the penicillin inhibition. In several cases spinal fluid for culture was taken both before and after withdrawing 10 to 15 cc. of fluid, but this did not result in a higher percentage of positive cultures. Identification of the meningococcus was carried out by gram-stained smears of the sediment and by typing. If moderate numbers of gram-negative diplococci were seen, direct typing by capsular swelling¹⁶ was attempted; otherwise, typing was done from the blood-broth culture on the following day.

Treatment

All cases were started on both intramuscular and intraspinal penicillin immediately after the diagnosis was made.

Intraspinal therapy. Initial intraspinal doses consisted of 10,000 to 20,000 units in 10 cc. of sterile physiologic saline solution, to replace a similar or larger volume of spinal fluid withdrawn. The spinal-fluid dynamics were tested before each dose was given to be sure that no block was present. From 5000 to 15,000 units of penicillin was then given intraspinally at twelve-hour intervals for two to five doses and every twenty-four hours after improvement was noted bacteriologically and clinically, and this dosage was continued until clinical and bacteriologic recovery took place. In some cases, the twelve-hour regime was resumed because of the poor clinical response and the persistence or recurrence of abnormal spinal-fluid findings. The number of intraspinal injections given each patient varied from three to eleven, averaging about six, and the total amount of penicillin given intrathecally varied from 30,000 to 150,000 units, averaging about 75,000 units.

Intramuscular therapy. Doses of 15,000 units were given intramuscularly every three hours in 7 cases and doses of 10,000 units every three hours in 2 cases. This therapy was continued until there were signs of definite clinical improvement. The duration of intramuscular therapy was two and a half to six and a half days. The total amount of penicillin given in each case by this route ranged from 190,000 to 1,155,000 units, averaging almost 500,000 units. In Case 7 on the thirteenth day and in Case 8 on the fourth day, because of poor clinical response and persistence of abnormal bacteriologic and spinal-fluid chemical findings, penicillin was discontinued and sulfapyrazine was given, first parenterally and then orally in standard doses. Case 1, because of persistent positive throat cultures after one week of penicillin therapy, a four to eight-hour course of sulfadiazine was given orally. No other specific therapy was used.

RESULTS

The relevant findings in the 9 cases are summarized in Table 1 and in the accompanying charts (Figs. 1-7). In all cases except Case 9, a Group I meningococcus was isolated from the spinal-fluid sediment, and in 5 cases the same organism was

FIGURE 1. Case 1.

In this patient the meningeal infection was not controlled bacteriologically or symptomatically until after the fourth day of penicillin therapy. Nasopharyngeal cultures still yielded copious growth of Group I meningococci after a week of intramuscular and intrathecal therapy and after frequent spraying of the nose and throat with a penicillin solution for twenty-four hours. Negative cultures were obtained after one day of sulfonamide therapy.

covered from blood cultures. In 4 of 7 patients in whom nose and throat cultures were made, a Group I meningococcus was also isolated from the na-

harynx. One patient (Case 9) who had received a single oral dose of sulfadiazine before entry had negative spinal-fluid and pharyngeal cultures, even though para-aminobenzoic acid had been added to the culture medium.¹⁷

Clinical Response

In 6 cases, improvement was first observed in one to five days after treatment was started, averaging

FIGURE 2. Case 5 (left) and Case 2 (right). Each patient showed a prompt bacteriologic response to intramuscular and intrathecal penicillin therapy, but the fever and symptoms persisted for several days.

about three days, as shown in Table 1 and Figures 1 to 5. In Case 7 (Fig. 6) there was a clinical recurrence on the twelfth day, and in Case 8 (Fig. 7) one on the fourth day. The clinical course did not justify continuance of penicillin therapy in these cases and sulfapyrazine was substituted. Response to the sulfonamide therapy was striking and occurred within twelve to thirty-six hours. In Case 9 (Fig. 5), in which sulfonamide therapy had been given before admission, the patient responded favorably after twenty-four hours of penicillin treatment.

The 6 patients treated only with penicillin became afebrile in five to fifteen days, the average being almost ten days. In Case 9, the fever lasted only three and a half days, which was less than in any other case in the series. In Case 7 it continued for only twenty-four hours after sulfonamide therapy was started, and in Case 8 for fifty-two hours.

Bacteriologic Response

Spinal fluid. In 2 of the 8 cases with positive cultures before treatment, the meningococcus could not be cultured at the time of the second lumbar puncture twelve hours after the start of therapy. In 4 cases, cultures of the cerebrospinal fluid re-

mained positive for twenty-four to sixty hours. In Case 7, the culture was positive after twelve hours, and later specimens showed gram-negative diplococci on smear on the fourth and seventh days, along with a recurrence of abnormal chemical findings. Growth in cultures was then obtained on the twelfth and thirteenth days. In Case 8, the last time growth of meningococci was obtained was after twelve hours, but positive smears were found after ninety hours.

Blood. In all 5 patients with positive blood cultures on admission, all subsequent cultures were negative. The second blood culture was always taken ten to twelve hours after the start of therapy.

Throat. Repeated throat cultures were made in 2 of the patients whose initial cultures were positive. The last positive culture in one of them (Case 8) was obtained after three days, and in the other (Case 1) after seven and a half days of intramuscular penicillin (660,000 units). In the latter, the culture was still positive after twenty-four hours of throat and nose spray with penicillin (400 units per cubic centimeter every two hours during the day and three times at night). In both the patients, the throat cultures became negative for meningococci within forty-eight hours after sulfadiazine was given orally in therapeutic doses.

Clinical and Cytologic Response of Spinal Fluid

As evaluated by the protein and sugar levels and the number of cells and their differential count,

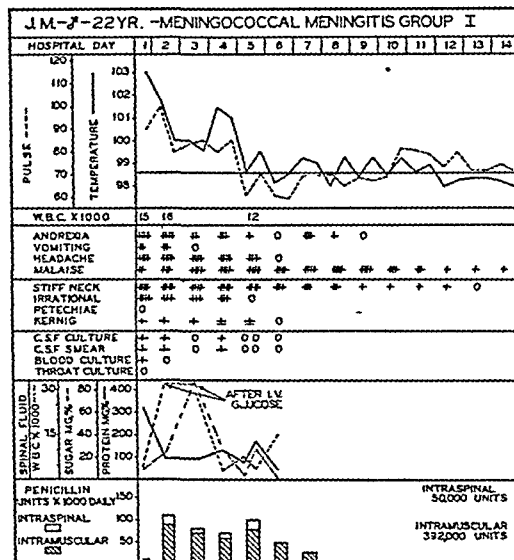

FIGURE 3. Case 3.

Cultures of the cerebrospinal fluid in this patient did not become negative until the fifth day of intramuscular and intrathecal penicillin therapy. During that time the patient continued to be irrational; he improved slowly thereafter.

the spinal-fluid findings returned approximately to normal in two and a half to eight days, with an average of five and a half days.

Complications

No complications occurred that could be attributed to the calcium salt of penicillin except possibly a scarlatiniform rash that appeared in 1 case on the fourth day of penicillin therapy. It is possible, however, that this rash was a result of erythro-

FIGURE 4. Case 4.

In this case, cultures of the spinal fluid were still positive on the third day. The patient was definitely improved after twenty-four hours but continued to have some meningeal symptoms for several days.

toxins derived from extensive herpes lesions that were secondarily infected with *Staphylococcus aureus* at the time of onset of the rash. In Case 5, there was a thrombophlebitis on entry, which became worse on the third hospital day and persisted through the twelfth day. One patient (Case 6) had a convulsion eight hours after the first intrathecal injection. This was probably due to increased cerebrospinal-fluid pressure, which may have resulted from the penicillin injection.¹⁸ In Case 7, there developed signs of consolidation of the left lower lobe, and many Type 8 pneumococci were identified in the sputum thirty-six hours after the intramuscular penicillin therapy was stopped. This complication failed to respond clinically or bacteriologically to doses of 15,000 units of penicillin given intramuscularly every three hours for forty-eight hours. One patient (Case 9) developed arthritis of the right knee on the third hospital day; on the ninth day, this was tapped and culture of the fluid was sterile.

Tests for Sensitivity of Strains

The strains of meningococcus recovered from 5 patients in the present series were tested for sensitivity to penicillin according to the method used by Rammelkamp and Maxon.¹⁹ One strain was

completely inhibited by 1.25 units per cubic centimeter, 3 by 0.625 units, and 1 by 0.312 units. The latter was obtained from Case 1, and the organism obtained after one week of penicillin therapy in this case was also tested and showed no increase in its resistance. This range of sensitivity puts these particular strains in a category with the more resistant strains of *Staph. aureus* and *Streptococcus viridans*.

All five strains failed to grow in peptone-fructose synthetic media containing 1 mg. per 100 cc. of sulfadiazine. This may be taken as an indication of the great sensitivity of these strains to sulfadiazine in vitro.

Penicillin Levels

Spinal-fluid levels of penicillin, tested by the Rammelkamp and Maxon¹⁹ method of serial dilution against a stock strain of streptococcus, varied within wide limits. They showed that the level

FIGURE 5. Case 6 (left) and Case 9 (right).

In Case 6 the patient continued to have positive blood cultures (Group I meningococci) for twelve hours and positive spinal-fluid cultures for thirty-six hours after intensive intramuscular and intrathecal penicillin therapy. He remained acutely ill for about five days, after which he steadily improved. In Case 9, the clinical features were characteristic of cerebrospinal fever but all cultures and smears taken on admission were negative for meningococci. It was later learned that this patient had received a single dose (2 gm.) of sulfadiazine shortly before being sent to the hospital, and blood taken on admission showed a free sulfadiazine level of 2.4 mg. per 100 cc. Definite clinical improvement occurred within twelve hours and continued steadily thereafter.

obtained in the lumbar canal eight to twelve hours after intraspinal injections were more than adequate for bacteriostasis.

COMMENT

Smith et al.²⁰ reported 43 cases of meningococcal meningitis treated with sulfonamides. Twenty were Group I infections, and 5 of these patients died. In 14 cases in which the clinical response could be

evaluated, the average time between the initial dose of sulfonamide and clinical improvement was one day. Fever persisted for an average of five and a half days after the onset of treatment. In 11 cases, negative cerebrospinal-fluid cultures were

a mortality of 3.1 per cent, and Appelbaum and Nelson²¹ reported a 1.4 per cent mortality in 141 consecutive cases treated with sulfadiazine and its sodium salt.

The results in the 8 cases reported here in which no sulfonamide therapy had been given previous to admission show clearly the poor clinical and bacteriologic response to calcium penicillin obtained in cases of Group I meningococcus meningitis as compared with sulfonamide-treated cases. In this series, it is impossible to evaluate the effect of the intraspinal therapy in relation to the severity of infection on admission and to the duration of illness before treatment. From bacteriologic sensitivity tests and from observed spinal-fluid penicillin levels, it can be assumed that many more times the bacteriostatic level of penicillin was obtained for at least twelve hours after its installation in the lumbar canal. The most probable explanation offered at present is, first, the failure of penicillin to penetrate to any significant extent into the cerebrospinal fluid from intramuscular or intravenous administration, and second, the failure to obtain a proper distribution of penicillin throughout the cerebrospinal fluid after intraspinal injection, thus preventing contact of the drug with many of the organisms. This may serve to explain the per-

FIGURE 6. Case 7.

In this patient the infection was not controlled clinically or bacteriologically after nine days of intensive intrathecal and intramuscular penicillin therapy. On the second day after intramuscular injections were discontinued, the patient developed lobar pneumonia of the left lower lobe and a copious growth of Type 8 pneumococci was obtained from the sputum. Resumption of penicillin therapy failed to control either the meningeal or the pulmonary infection. Clinical improvement began within a few hours after sulfonamide therapy was started, and the patient had essentially recovered thirty-six hours later.

obtained twelve to eighteen hours after the start of therapy and in the remaining 3 the cultures were positive for seventeen to twenty-four hours. Banks²¹ in a series of 72 cases treated with sulfanilamide and M. & B. 693 without antiserum noted that the acute symptoms disappeared rapidly and the temperature in most cases returned to normal in two to six days. In 66 patients the spinal fluid was sterile in twelve to twenty-four hours and in 4 it became sterile in twenty-four to forty-eight hours; only 1 patient was found to have a positive fluid after forty-eight hours. Spinal-fluid cell counts fell to below 500 in three or four days, and 90 per cent of the cells were mononuclears in five to six days.

The efficacy of the sulfonamides has been shown in a review of mortality rates by Dingle and Finland.²² In over 1000 cases treated with sulfanilamide there was a mortality rate of 1.4 per cent; in 700 cases treated with sulfapyridine and 26 treated with sulfathiazole it was 8 per cent. Recently, in a series of 129 sulfadiazine-treated cases of meningococcal meningitis, Marangoni and D'Agati²³ reported

FIGURE 7. Case 8.

This patient remained acutely ill and irrational during four days of therapy with penicillin intrathecally and intramuscularly. Because he was obviously getting worse clinically, sulfonamide therapy was then given. Improvement began within a few hours and steadily continued.

sistence of exudate and consequent pocketing-off of organisms, adhesion formation and pressure difficulties. The rapid and complete distribution of the

sulfonamides throughout the cerebrospinal fluid of six taps were done in addition to occasional unsuccessful ones. This factor makes management by post-mortem studies. This may explain the difficult as compared with sulfonamide administra-

much more favorable clinical and bacteriologic response to the sulfonamides.

In these patients the number of lumbar punctures in each case varied from three to eleven. An average

tion, in which often a single diagnostic puncture is all that is necessary.

Meningococcemia, on the other hand, seemed to respond rapidly. The persistence of positive throat

cultures in one case for four days and in another until sulfadiazine was given on the ninth day reveals another possible disadvantage of penicillin therapy.

fections. Cheever et al.²⁵ in a study of 161 cases of meningococcal infections of the nasopharynx showed that nasopharyngeal cultures became negative for

TABLE 1 (Continued).

Case No	RESPONSE TO PENICILLIN THERAPY						COMMENTS, COMPLICATIONS AND SO FORTH

9			0		1½	3½	Arthritis in right knee 36 hr after entry (first tap, on 9th day, sterile), blood sulfadiazine on admission 2.4 mg per 100 cc (patient had received one oral dose 2 to 3 hr before entry)

†The numerator indicates time (at or after admission) of last positive culture, and the denominator the time of the first subsequent negative culture, 0 indicates that all cultures were negative, and — that no cultures were taken

‡The intervals represent the time after the first dose of penicillin

Adequate bacteriostatic levels of penicillin probably did not reach the nasopharynx in these cases. This certainly is another important consideration favoring the use of sulfonamides in meningococcal in-

meningococcus in all cases within seventy-two hours after a dose of 8 gm of sulfadiazine. This has now been adequately confirmed, even with smaller doses^{26, 27}

The possibility that the calcium penicillin used in the present cases was inferior in its therapeutic effects was considered. This seems unlikely for the following reasons. In vitro tests indicated full activity, in Oxford units, against standard strains of other bacteria. The same batch of calcium penicillin was given at the same time to a much larger number of patients with various other diseases, including cases of pneumococcal meningitis, with results comparable to those obtained with similar amounts of sodium penicillin. Intrathecal injection of the same lot in other subjects gave reactions that were actually slighter than those obtained with similar amounts of sodium penicillin. There were no local reactions from its use intramuscularly.

If good results are obtained from the treatment of meningococcal meningitis with penicillin, one must suspect that the patient has received sulfonamides before entry. He is not always in a condition to give a history of such therapy. The potent bacteriostatic effect of these drugs on the meningococcus is such that even one or two small oral doses may suffice to produce a complete bacteriologic and clinical response, as indicated by the experiences in the Anglo-Egyptian Sudan in 1938.^{28, 29} This was probably the factor that contributed to the rapid and favorable response observed in Case 9.

A comparison of the results of therapeutic studies on meningococcal infections in mice lends further support to the greater effectiveness of sulfadiazine *in vivo*. Thus, in contrast to the 1800 Oxford units used by Dawson et al.,⁵ as mentioned at the beginning of this paper, Thomas and Dingle³⁰ protected mice against similar infections with ten to ten thousand times the 50 per cent lethal dose of a virulent Group I meningococcus by giving only a single dose of 0.0025 mg. of sulfadiazine. For the average adult patient, these doses are equivalent, weight for weight, to about 10 mg. of sulfadiazine and 7,200,000 units of penicillin. The two studies are not entirely comparable, but the figures are certainly impressive when considered together.

Lastly, the finding in five consecutive cases of strains of meningococcus that are relatively resistant to penicillin seems to be in marked contrast to the results reported by others. Great differences in susceptibility to penicillin must occur and should be further investigated. These findings may explain, in part, the poor results obtained in this series.

CONCLUSIONS

The clinical and laboratory findings in this series of 9 cases of meningococcal meningitis treated with calcium penicillin, when viewed in the light of the accumulated results of sulfonamide therapy, suggest that the sulfonamides are the drugs of choice in the treatment of Group I meningococcus meningitis, and that penicillin may be effective in Group I meningococcus meningitis in the doses used, but

that the response is less favorable than that from sulfonamide therapy.

If penicillin is used, careful observations should be made of the clinical course, the spinal-fluid and nasopharyngeal bacteriology and the spinal-fluid chemistry.

The clinical response to penicillin is slower than that to the sulfonamides; abnormal spinal-fluid chemical and bacteriological findings persist longer, there may be recurrences; the meningococcus-carrier state may persist; the treatment is difficult, and, finally, one may eventually have to resort to the sulfonamides for cure.

Calcium penicillin seems to be quite effective against Group I meningococcus bacteremia.

Strains of Group I meningococcus vary markedly in their susceptibility to penicillin. In this respect, the strains studied in the present series resembled the relatively resistant ones of *Staphylococcus aureus* and *Streptococcus viridans*.

Several significant papers bearing on the present subject have appeared since this one went to press. Miller and Foster^{31, 32} reported favorable responses in vitro and in experimental infections with meningococcus, but special methods were required for this purpose. Rosenberg and Arling³³ used sodium penicillin in the treatment of 71 cases of meningococcal meningitis and meningococcemia without meningitis and noted favorable clinical responses, but many of the bacteriologic responses were similar to those reported here. Their general method of treatment was similar to that used in this series except that more thorough drainage of the spinal fluid was done before each intrathecal injection of penicillin. The authors, however, do not mention how frequently sulfonamides were used in their cases, and no mention is made of any special effort to determine that point. Only in the single fatal case is it noted that the patient received both sodium sulfadiazine and penicillin. From observations in our clinic and from many reports in the literature, particularly the experience in the Sudan,^{28, 29} it is to be expected that a single dose (2 or 4 gm.) of a sulfonamide given by a medical officer in a dispensary at the time when the diagnosis is suspected would be adequate to bring about most of the beneficial results. Rosenberg and Sylvester³⁴ were able to recover penicillin from the spinal fluids of cases of meningitis in concentrations of 0.03 to 0.35 unit per cubic centimeter after intravenous or intramuscular injections of 20,000 to 40,000 units. If this is corroborated it may prove possible and desirable to eliminate intrathecal therapy in some cases of meningitis and thus to avoid one of the major objections to the use of penicillin in these cases. Actual experience in treatment of cases of meningitis with penicillin alone would not seem to bear out this expectation.

ARE DOCTORS PEOPLE?*

ROGER I. LEE, M.D.

BOSTON

IN MANY of the folklores, the doctor, or rather his analogue or prototype, appears as being quite set apart from ordinary people. He is seen in many forms and guises. If there is a touch of the lower animal about the medicine man, there is more of the deity. There is more of the saint than the devil, but some of both. There is madness, witchcraft and chicanery, but there is a larger amount of wisdom, sanity and honesty.

Of course primitive people merely created out of their own composite experiences — emotions, desires, fears and joys — their own gods, devils, saints, medicine men and various other important figures in their daily lives. Once the pattern was roughly established, there was a strong tendency to continue the type. But each medicine man used his own imagination, his own personality, good or bad, his own experience and a few of his own tricks to alter the pattern somewhat.

Strong members of the community or tribe always attempted to use the medicine man for their selfish ends. Sometimes they succeeded, sometimes they lost, and sometimes there was a new medicine man. Likewise, strong men would find that at times the gods were wholly co-operative, as we may call it. If there were priests of one kind or another who divulged the pleasure or displeasure of the gods, the priests might be persuaded to make a somewhat different interpretation, or possibly the strong men might do their own interpreting and find it easier to head both the spiritual and the temporal organizations. This was rarely done in

the case of the chieftain and medicine man, but the union of the priest and medicine man sometimes happened.

No brew of medicine, however, no matter how cunningly concocted, even in the most favorable phase of the moon, or even if subjected to the loudest of incantations, can heal certain mortal wounds or cure certain mortal diseases. Nor can such a brew restore a lost limb, eyesight or hearing. Nor can it replenish the ravages of time, more particularly in those feats of prowess fostered by the gods and goddesses of war and love. Thus it often seemed the part of discretion, if not of wisdom, to leave the medicine man, so to speak, on his own. If his brews, medicines and incantations were not satisfactory, one could try the potions and performances of another medicine man, perhaps one in a near-by community, perhaps one in a distant community, who had a reputation for healing certain ailments, or perhaps an upstart competitor in the same community.

Well, has the situation changed very much fundamentally? Patients get dissatisfied and seek help in distant places now as they did in the days of medicine men, perhaps as far from Worcester as Boston, New York or Rochester, Minnesota.

The community gets about the sort of medical practice it really wants and creates. At times the doctor is better than the community deserves, but in a small community especially, the medicine man of old and the doctor of today are quite at the mercy of malicious gossip. Of course, it is true that whereas the doctor gets blamed for many circumstances and accidents over which he has no control, he is also praised for certain happy outcomes to

*An address given by the president of the Massachusetts Medical Society at the one hundred and fiftieth anniversary of the Worcester District Medical Society, Worcester, May 10, 1944

which he contributed nothing—even though the balance is favorable to the doctor. Such a situation is stupid and wholly harmful. In the more recent but still bygone days of the apprentice method of education of the doctor, the old doctor passed on to his apprentice the secrets and tricks of his practice. Those were the days of rugged individualism of the doctors. It was this type of family doctor who caught the imagination and acquired the affection of a grateful community. Perhaps his practice of medicine was not perfect. Perhaps only sometimes did he bring cure, but he always brought comfort, physical and mental, to the patient and his family. In the modern days of formal medical education, medicine is far, far better, but it is not now free and independent. It is less so than in the days of the family doctor. Unfortunately or fortunately, as you will, medicine is now under the profound influence of lay opinion and lay action. The controlling bodies of educational institutions are naturally largely composed of laymen, that is, so far as medicine is concerned. Furthermore, there is a further lay and, at times, political control of the funds of some of the state medical schools. Of course the situation varies, but the president of a state university has to spend much time defending his budget before legislative committees. Some of these legislators have extremely positive ideas in regard to education, including medical education. The rejoinder is obvious, namely, that the president of a privately endowed university spends his time in argument with possible benefactors instead of with state legislators; and benefactors, like legislators, have their prejudices. In other words, the community still creates the medicine man in the image and in the pattern that it conceives to be the kind that delivers the most effective brew.

Now, this concept is not entirely whimsical, because it was not so long ago that a health officer found himself in jail for having ventured to diagnose a case of bubonic plague. That part of the country would not admit the existence of plague, and that was that. Of course the disease was not plague, and the doctor got out of jail, but after all, it was a lay resort to coercion in an unpleasant dilemma. It was merely the old story in a new setting: the tribal chief was sterile and his favorite wife was pregnant. Medical truth in the early days bowed to social convention, and today sometimes has to give a nod if not to turn a deaf ear.

Leprosy is a terrible disease, and no one wants to catch it. Consequently, because you and I do not want to have it, in our lay capacities we permit the unfortunate victims of this disease to be segregated on lonely islands. Such is the law and the practice. The truth is that leprosy is not especially contagious. Such barbaric cruelty is unjustified by the known medical facts.

These illustrations could be multiplied many times, merely adding more evidence of the dominance of the community over the medicine man. But it is not solely the dominance and control of medicine by the community that I want to discuss. We must accept the fact that the community, from the days of folklore and the medicine man to the present, conceives the medicine man and the doctor as someone apart from the rest of the tribe or the rest of the community. In the old days the medicine man often lived apart, painted his face egregiously and wore extraordinary masks. As a part of his performance he went through grotesque gyrations and gymnastics. Within the memory of many listeners, doctors wore an affair called a "Prince Albert" or frock coat. Certainly doctors were then, even more than now, rugged individualists, and I cannot visualize a convention of doctors setting up the Prince Albert coat as a sort of uniform for the profession. Consciously or not, the wearing of it was a dictum from the community. And take the gold-headed cane of another era. I have always maintained that the only practical use of the gold head was for the physician in those days to thrust it into his mouth to prevent his making any more of an ass of himself than he had already.

An erstwhile intern of mine in another city replied to my remark that because he drove such a luxurious car he could not be doing so badly financially. "In this city, patients will not go to a doctor who drives a Ford. I know because I tried it, and all my good friends and good patients spoke to me about it." I was about to make some remark more emphatic than polite about that city and state when it occurred to me that I had intended to ask him how he liked his office in an office building, since I was considering moving my office to a similar building in Boston. Such a building had, at first anyway, to be within a very restricted area—just the opposite of course, to the red-light district in character but really having the same implications. Of course, if one is famous like the Mayos, it makes no difference where one's office is. I know a doctor who receives his patients in bathing suits on the sand under a sun umbrella, but the locality is Palm Beach, and the doctor is a neuropsychiatrist.

Not long ago, a United States senator telegraphed that twenty doctors were needed at once for a war-boom town in his state. By the time the "sob sisters" in New York City got through with the story, it was two hundred doctors. There was no information about the kind of doctor wanted. It turned out that probably two doctors were required for a manufacturing plant—one a general practitioner and the other a physician with some knowledge of industrial medicine. The plant had been running for several months, and although its operator had not forgotten about his contract,

his site, his men or his materials, he had forgotten the doctor.

One is always hearing of large areas without a doctor. I have traveled through some of those large areas, and there appeared to be little worth while in them, except the train I was riding in. Whole counties in Kentucky do not have a doctor. I used to be dismayed by this until I learned how many counties there are in Kentucky. I have forgotten the number, but it is well up in three figures. What kind of doctor do people want in the mountains of Kentucky and Tennessee? Certainly not a "damn Yankee" doctor. He would not get a chance to practice. A native doctor could practice, but he could not be paid because there is nothing to pay him with. Incidentally, there is no provision in the Wagner-Murray-Dingell Bill that includes these people; it provides only for industrial people, for whom it is compulsory.

As one goes through Massachusetts one finds small settlements, often a so-called "village," without any doctor. One looks at the deserted mills, the deserted farms. One hears someone say, "Most of the people have left, but you'd think some doctor would come." Are doctors people?

Years ago I was on a committee that attempted to study the distribution of doctors, especially in rural communities. We tried to collect cases of hardship, lack of care and forced neglect, but could find only one such case. The complainant was a farmer who testified that on such and such a day he tried to get a doctor to come to see his wife but the doctor would not come. It was in the winter and in the night. His wife had been sick for a couple of weeks but was in "great pain." Somehow or other she got over her illness, but it was terrible, and we were told "Doctors ought not to be allowed to get away with things like that." So we got hold of Doctor Blank. He knew this farmer and occasionally treated him or some member of his family. He had a general idea of where the farmer lived. He was at first rather puzzled by the tale, but finally said:

I'm sure this is the story, but you had better check it with the farmer. It was midwinter and snow was falling. I had just gotten in from a confinement case. After a telephone argument over how sick the wife was, I finally said I'd come, that I would follow the plow the next trip to such and such a corner where the farmer would meet me with a horse and sleigh. That was a common arrangement. However, the farmer said, "Go out on a night like this? I would not send a dog out." Whereupon I hung up.

Subsequently, the farmer verified the complete story, adding that he was tired. To the remark that the doctor might be tired too, he merely replied, "Oh, they get used to it, and if they can't, they ought to do something else."

Now, the Christian Scientist decidedly poohpoohs some of the material things in life, but the "reader" is sound and safe in situations like the

foregoing, because he or she gives the patient absent treatment and does not have to go out in the blizzard of a winter's night.

Just now the armed forces want doctors, physically active ones, for our boys, and the war industries want industrial doctors, while the good folks at home get along courageously with self-rationed medical advice and treatment.

There seems to me to be much too much talk that a doctor is demanded here or there, on this mountain or at this village corner. If doctors were turned out on assembly lines in mass production, it might make sense to talk of so many here and so many there. Of course, the product would be mechanized. What is wanted are good doctors, skilled doctors, not by any means always specialists, but "regular-guy" doctors.

Doctors are human beings notwithstanding the fact they are not supposed to be tired, to have vacations or to enjoy uninterrupted dinners or golf games. For months, on the front pages of most daily newspapers, appeared statements of how soon the draft would begin to take fathers. Senators and representatives in Congress announced that they would fight — in Washington, D. C., not in uniform — to the last ditch the drafting of fathers. Doctors, being ordinary people, seek to marry beautiful and intelligent girls. Doctors' wives have seen their husbands volunteer, even before Pearl Harbor, and leave their homes and children. Many of them have been over thirty-eight and even over forty-five. But doctors were not supposed to object. Since the good women are also human, they sometimes object, but the doctor goes. When the war is over, he will not come back to that salary and that pension, but will be obliged to build up his practice all over again in a world that believes that it created doctors in a certain pattern and therefore can destroy them.

After the war, history will tell of great medical discoveries in it. Plasma and penicillin will be cited. There cannot be found better illustrations of lay domination of medicine. To all intents and purposes, plasma and the theory of plasma was "frozen" — to use the modern jargon — from the end of World War I to the beginning of World War II. Twenty years after World War I, medical scientists continued working as if those twenty years had not existed. The story of penicillin is more picturesque. In 1928, Professor Alexander Fleming, of London, made the observation that germs would not grow with or close to the colony of a common mold. Doubtless other men had observed the same thing, but Fleming puzzled over it and finally published this observation. Years went by and nothing happened. Fleming once showed this phenomenon to me, as he did to many others. Certainly something ought to have been done about it. It was only the threat of war and war itself that furnished the impetus that has produced penicillin. You would

not believe, if I told you, the number of millions of dollars poured into the development of penicillin. It is a new agent in combating infections. It may be that we shall be disappointed in the final place of penicillin, but its present promise dazzles the imagination. And yet without the war no man can ever know whether penicillin would have been developed or how many years it would have taken to develop it. Once again, I must point out to you that the doctors are not the masters of medicine or medical practice, even today.

Certainly the legislature of Massachusetts years ago inflicted a terrible medical practice act on this state, and for years the sovereign Commonwealth of Massachusetts has been the dumping ground for incompetent doctors who were not allowed to take or could not pass the examinations in any other state. Finally the stench reached the Legislature, which recently framed a good bill. But it took a courageous minority of the Board of Registration in Medicine, including fine Dr. Atwood, of Worcester, and a courageous governor to complete the cleansing process of the Augean stables. But what of the hundreds of incompetents who *bought* their licenses to practice medicine in Massachusetts? Thus, it is not the good doctors who determine the standards of medical practice but the community itself. It perhaps creates the doctor in its own image, which can be evil.

It has been to the everlasting credit of the medical profession of this country that traditionally doctors do not patent their discoveries. Recently there has been some wabbling in this attitude. Curiously enough, some medical schools have sought to profit — and some of them have done so mightily — by taking over the patents and the royalties therefrom. The story is told of the opening of the new Harvard Medical School about 1905. A famous New York banker had been a very generous benefactor, but universities are always venal and grasping. The university's star beggar took the New York banker around. The beauties of the buildings were appropriately described. The young scientists were likewise duly noted. "Alas!" said the beggar, "If only we had a little more money to put these trained young men to work." "Humph!" said the banker, "If you have the space and the bright young men, why don't you have one of them invent a good patent medicine? That gives bigger returns than anything I know."

I should like to talk at great length on medical patents and their iniquities, but God be praised, an important court has held a patent that benefited one medical school as invalid, and President Robert Hutchins, of the University of Chicago, has come into the fold of patent purity in medicine. When I am finally sure that any scientist can work with scarlet fever, its germs, its toxins, its antitoxins and its antisera without a special license from the University of Chicago committee on

whatever they call it, I shall write President Hutchins a nice letter congratulating him on seeing the light. But, mind you, this only illustrates the possibilities of lay domination of medical science in accordance, no doubt, with the best Christian practices in business, but leaving the medical men merely puppets.

Now, God forbid that doctors should organize a union, even if that action exempted them from the operation of the anti-trust laws. We do not want any Little Steel Formula. There is too strong a possibility that the other fellow might have a different spelling of "steel."

As I have tried to point out, the lay domination of medicine has been going on since the beginning of time. The medical profession has at times approached independence but it has never been free, certainly not in the way that the profession of law has been independent and free, and master of itself.

Over the years since the turn of the century, there has developed a trend, not new, but for the first time really powerful, that represents a new social philosophy. It came into full flower when social sciences were reorganized as a separate sector of human experience and human knowledge. The enthusiasts of this school of thought lump more or less all the human miseries together. Whereas the doctor looks at his patient through a microscope, the social scientists look at illness through a telescope. Perhaps Sir William Beveridge can be regarded as one of the most articulate, most logical and most reasonable of the exponents of this new social philosophy. He has five giants that must be overcome on the way to "reconstruction," as he calls it — "millennium" is my humble contribution in words. These giants are Disease, Idleness, Ignorance, Poverty and Want. There are other thinkers, perhaps on the outskirts of this philosophic trend, who would mention Superstition, Prejudice, Selfishness and Greed. Within the fold of this cult, however, poverty is the mother of disease. The paternity of disease is usually left obscure. These social scientists would therefore take over disease — the study of disease, the prevention of disease and the treatment of disease — and make themselves masters of medicine and the medical profession. Now, lest you think I am entirely mad, I hasten to add that this, I find, is a favorite theme of a Jesuit priest, Father Schwitalla, who happens to be dean of the St. Louis University School of Medicine, and president of the Catholic Hospital Association of the United States and Canada.

Some years ago I found Professor George Foot Moore, perhaps then Harvard's greatest scholar, in something that in anyone else than a professor and an ordained minister would be called a rage. He had been examining students for the degree of doctor of philosophy. A colleague gave the student a somewhat lengthy case history, which Professor

Moore said was the story of a bum, a very ordinary man. The student candidate was asked for his social diagnosis. When the student answered, "Frustrated childhood in an environment of poverty," Professor Moore exploded. Doubtless there are frustrations, doubtless there is poverty. But I agree with Professor Moore that there are also probably bums, and with Prime Minister Winston Churchill that there are also pub crawlers.

In any event, the social scientist would put disease and the medical profession within the Social Security Act, with a social scientist in the Cabinet. As is evidenced by the Wagner-Murray-Dingell bill, the problem is regarded as economic. Curiously enough, what they want to toss at this hungry, poverty-stricken and diseased wretch is medical service. Now, most doctors would like, so far as possible, to separate the economic and medical aspects. So far as I know, no substantial group of doctors is opposed to the control and relief of poverty, unemployment and the distress of old age, and in the control and relief of poverty doctors would include shelter, warmth, food and the like. And certainly doctors want to have not a better but the best distribution of medical care or "medical service" if you like the new jargon. To the doctor human beings are living entities, not case numbers on a blueprint. Likewise a doctor is a human entity. He is no blue-headed pin to be stuck in a map to take care of so many red-headed pins representing patients.

We all know that in some respects mechanized medicine will work fairly well. You can take the urine of a woman down to the laboratory, and some little laboratory animal will whisper to you whether the woman is pregnant or not. But, for heaven's sake, be careful not to get the bottles mixed. And the impersonal laboratory said authoritatively that Charlie Chaplin was not the father of a certain child. But the mechanization of medicine can be carried too far, and it will be if this present trend continues.

Doctors seem always to have been dominated by others and never to have been complete masters of themselves and of their profession. It seems that this present trend of social, economic and political philosophy threatens them with more dominance than they have ever known. Although I believe this to be a menace to the grandest profession in the world, who am I to venture upon prophecy?

Please note the humility and the altruism of the doctors of Worcester who founded this society one hundred and fifty years ago. This was, a collection of men who planned not to aggrandize themselves but rather to improve themselves, and thereby to benefit the whole community.

Of the same temper are the words in the charter of the Massachusetts Medical Society and that of the American Medical Association. As a class, the doctors have not wanted to run the rest of the world. The late President Lowell, of Harvard, said with regret that the doctor was too busy and too occupied by keeping abreast of the extraordinary medical advances to participate as he should in public affairs, and that the public was greatly the loser thereby. Nevertheless, the public has always wanted its doctors "straight," if you understand that drinking term. The public looked down its nose, and still does, at literary doctors or artistic doctors. And the doctor has shown that he is human and like other folks when he indulges in literature, art or music, usually almost secretly.

But this is not a clarion call for the doctor to dominate the world. Anyway, he knows people too well and himself too well. In his more robust and more individualistic moments, the doctor would like to be more master of his fate and his destiny. But no pedestal for him. In these days of so many words written and spoken about freedom and security, he would like a bit of that freedom in his work. And as for security, his experience makes him skeptical. He has seen diseases vanish and new diseases appear. He has seen trusted remedies become obsolete; he has seen the strong die and the weak get well; he has seen the rich become poor and the poor become rich. He knows that the world is a better and more healthful place in which to live than it was, despite wars, taxes and a large collection of pet hates and aversions of his own.

And so let us turn to a pleasant scene of two elderly doctors, fishing and talking. The fishing was not very brisk, but the talk was brisk and at times salty. Both doctors agreed that the world was in a hell of a mess and what had not already gone to hell was on its way there. Finally one doctor said to the other, "And I suppose if you had your life to live over again, and even knowing what you do, you would be just damn fool enough to be a doctor, the same kind of a doctor, and live the same life." The other doctor answered, "Yep, I suppose so, but I think I'd do more fishing."

CARDIOSPASM AS A CAUSE OF PNEUMONITIS*

WILLIAM GRAY, M.D.,† AND I. R. JANKELSON, M.D.‡

BOSTON

CARDIOSPASM results in dilatation and elongation of the esophagus and a secondary esophagitis caused by a variable degree of food retention. Whenever ingesta are retained in the esophagus, — and in cardiospasm the capacity of the esophagus may be a quart or more, — there is danger of inhalation of food, saliva or secretions, which may lead to the development of an inhalation pneumonia, lung abscess, chronic bronchitis or bronchiectasis.

Jackson and Jackson¹ have rightly emphasized that such inspiration is especially likely to occur with obstruction in the upper portion of the esophagus, particularly in the presence of a carcinoma. They describe nine means by which pulmonary symptoms can be developed by pathologic conditions in the esophagus. Of these only one applies to cardiospasm. The pulmonary involvement secondary to a pre-existing cardiospasm is due to regurgitation of food or secretions, which is particularly prone to occur during sleep when the normal protective reflexes are less sensitive. Thus food particles from the large reservoir in the esophagus may be inhaled. Sudden awakening with coughing, choking and strangling is not infrequent in cases of esophageal food retention. Moreover, Rastelli² and Camiel and Loewe³ demonstrated by roentgenoscopic and roentgenographic methods frequent spilling of barium into the trachea and bronchi in obstructive lesions of the esophagus. This demonstrates that inspiration of food and secretions may occur during waking hours as well as in sleep. It is likelier to occur in debilitated, emaciated and dehydrated persons, whose reflexes, like all other body functions, are less active than those of others. Minimal inspiration leads to some strangling and coughing, and massive inhalation may lead to serious pulmonary disease.

Two such cases that recently came to our attention are reported below.

CASE REPORTS

CASE 1. C. T. (B. I. H. 71845), a 45-year-old, married woman, was admitted to the Beth Israel Hospital with a 4-year history of dysphagia and a 3-year history of vomiting and regurgitation. The vomiting occurred several times daily, the vomitus consisting of mixtures of partially digested and unchanged food. The patient frequently awoke from sleep to find her mouth full of regurgitated food, some of which had run out on the pillow. Attacks of sharp pain located in the midback region on the right side had begun 2 years previously, and as time went on this pain became more

diffuse and was transmitted to the right side of the neck. Four months prior to entry into this hospital, the patient developed a cough productive of large amounts of mucopurulent material, associated with pain in the bilateral posterior part of the chest and fever. Because of these symptoms she entered another hospital. During the next 2 months she had three attacks of fever, cough and chest pain, each episode lasting about 10 days. X-ray films of the chest taken at that hospital showed bilateral bronchopneumonic changes and although sputum and gastric washings were negative for acid-fast organisms, a diagnosis of pulmonary tuberculosis was made and the patient was transferred to a tuberculosis sanatorium for further care. During her 2-month stay there, almost continuous vomiting and regurgitation with progressive emaciation took place, and a fourth attack of high fever associated with cough, diffuse rales and patchy dullness in both lung fields occurred. This attack lasted for 9 days.

FIGURE 1. Roentgenogram of Esophagus (August 4, 1943). Fluoroscopic and roentgenographic examinations showed the esophagus to be markedly widened and tortuous. In this film the upper two thirds of the esophagus is mottled, owing to retention of food and secretions. These findings are typical of cardiospasm.

and did not respond to chemotherapy. Repeated sputum examinations were negative for tubercle bacilli.

Because of doubt concerning the accuracy of the diagnosis of pulmonary tuberculosis, the patient was transferred to this hospital for further study and treatment. At the time of entry she presented a picture of extreme emaciation, weigh-

only 85 pounds, whereas 4 years previously she had weighed 140 pounds.

Physical examination revealed an apprehensive woman with a rectal temperature of 102° F., a pulse of 110 and a respiratory rate of 32. The pharynx was diffusely reddened and showed considerable lymphoid hyperplasia. Examination of the lungs showed dullness to percussion over both sides, with crepitant rales over the lower part of both lungs, more marked on the right side than on the left. Heart sounds were hyperactive, and there was a harsh, systolic murmur heard best just to the left of the

on the basis of esophageal overflow, and she was placed on a regime of nothing by mouth, intravenous fluids, intravenous vitamins and intravenous sodium sulfadiazine. The temperature began to return to normal by the 21st day, and by the 24th day it was normal. On the 25th day, intravenous fluids and medications were discontinued and on the following day, esophageal bouginage, with Hurst bougies, was carried out. On the 27th day, the patient coughed up a tablet of phenobarbital that she had ingested 15 minutes previously. Bouginage was repeated on the 29th, 37th and 43rd days. Each time the esophageal bougies passed more easily than the time before. After each bouginage, the patient noted that less regurgitation of food occurred. The temperature remained normal until the 46th day. During that time repeated examinations of the lungs revealed only a few scattered rales.

On the 46th day, the temperature again rose to 104° F. and signs of extensive bronchopneumonia reappeared in both lung fields. Sulfadiazine was again started, but it was given by mouth, as were food, fluids and other medications. The diet consisted of fluids and semisolid foods only. The patient continued to run a spiking temperature with daily variations between 101 and 104° F. until the 59th day, when sulfadiazine was omitted. The temperature continued to be elevated until the 64th day, when it returned to normal, in association with clearing of the signs of pneumonia.

Bronchoscopy and esophagoscopy were carried out on the 56th hospital day. The only abnormal findings were a lack of active sensation and normal reaction against the procedure and cardiospasm, with atony of the esophagus. It was the opinion of the operator that the dilatation of the

FIGURE 2. Roentgenogram of Chest (August 4).

num in the 3rd intercostal space, but the heart size was within normal limits. Moderately severe clubbing of the fingers and minimal clubbing of the toes were present.

X-ray examination of the chest on admission showed findings consistent with bronchopneumonic consolidation in the right upper lobe and resolving patchy pneumonic consolidation throughout both lung fields. At the time this film was taken, it was noted that the heart appeared to be slightly rotated to the right. Because of this, the patient was sent to the X-ray Department on the following day for fluoroscopy of the heart. At that time a horizontal fluid level was seen in the upper posterior mediastinum. The patient was then given a swallow of barium and it was found that the esophagus was markedly dilated and tortuous (Figs 1 and 2). In report of this examination stated, "The convex contour previously interpreted as a dilated right heart, turns out to be the contour of the tortuous, dilated esophagus typical of cardiospasm." Only small amounts of barium were seen trickle through the cardia into the stomach. The stomach and duodenum were normal. Another x-ray film of the chest taken on the 10th hospital day showed no essential change from the previous examination. On that day the temperature rose to 104° F., with an elevation of the respirations to 50 and of the white-cell count to 20,000. Associated with this there appeared increasing signs of bronchopneumonic consolidation throughout both lungs. From the 10th to the 13th day, the temperature ranged between 101.0 and 105.5° F. X-ray examination of the chest on the 13th day showed markedly increased consolidation throughout the lower two thirds of both lung fields (Fig. 3). On the 16th day, it was finally decided that the patient had aspiration pneumonia

FIGURE 3. Roentgenogram of Chest (August 17).

This film shows increased density throughout both lung fields as compared with the previous examination. Definite consolidation is present.

esophagus, the cardiospasm and the lack of normal sensation in the esophagus and bronchial tree accounted for the spilling of food from the dilated esophagus into the respiratory tract.

X-ray examination of the chest on the 73rd day showed partial clearing of the pulmonary infiltration (Fig. 4). Fluoroscopic examination of the esophagus on the 83rd day still showed a dilated, atonic esophagus, but there was great improvement in the ease with which barium flowed from the esophagus into the stomach.

CARDIOSPASM AS A CAUSE OF PNEUMONITIS*

WILLIAM GRAY, M.D.,† AND I. R. JANKELSON, M.D.‡

BOSTON

CARDIOSPASM results in dilatation and elongation of the esophagus and a secondary esophagitis caused by a variable degree of food retention. Whenever ingesta are retained in the esophagus, — and in cardiospasm the capacity of the esophagus may be a quart or more, — there is danger of inhalation of food, saliva or secretions, which may lead to the development of an inhalation pneumonia, lung abscess, chronic bronchitis or bronchiectasis.

esophagus, the cardiospasm and the lack of normal sensation in the esophagus and bronchial tree accounted for the spilling of food from the dilated esophagus into the respiratory tract.

X-ray examination of the chest on the 73rd day showed partial clearing of the pulmonary infiltration (Fig. 4). Fluoroscopic examination of the esophagus on the 83rd day still showed a dilated, atonic esophagus, but there was great improvement in the ease with which barium flowed from the esophagus into the stomach.

The temperature remained normal from the 64th to the 86th day, when the patient was discharged. She stated that she felt much improved and that she was able to swallow more easily than she had for years. Furthermore, regurgitation of food was almost completely absent. During the hospital stay the patient gained 10 pounds in spite of the two prolonged attacks of aspiration pneumonia.

Four days after discharge, the patient again began to regurgitate and developed a temperature of 101.4° F., as a result of which she was readmitted. On examination only a few rales could be heard at the lung bases. The temperature returned to normal on the 2nd hospital day with the use of symptomatic therapy only. The patient was kept in the

FIGURE 4. Roentgenogram of Chest (January 19, 1944). This film shows considerable clearing in both lungs, consistent with resolving pneumonia.

hospital for 2 weeks, and throughout this period manifested no more signs of pneumonia and no further fever; regurgitation did not recur.

Three months after the second discharge, the patient was again seen in the Outpatient Department. She was still well and her weight had increased to 108 pounds, a gain of 23 pounds from the lowest weight 4 months previously. Some regurgitation was still present, but swallowing was much easier than it had been in the preceding 4 years. The patient reported that she had no trouble at all in swallowing liquid and semi-solid foods. X-ray examination of the chest still showed some scattered infiltration throughout both lung fields, which was interpreted as due to pulmonary fibrosis. Fluoroscopic and radiographic examination of the esophagus revealed continued improvement, but some retention was still present. During these 3 months, the patient had been completely free of fever and her cough had decreased markedly. Another esophageal bouginage was done.

CASE 2. M. E., a 34-year-old woman, had had a history of dysphagia for 10 years. The amount of discomfort varied from time to time, but she was never completely free of symptoms. The difficulty in swallowing was more marked when she partook of solid food. Liquid and mushy food was swallowed with little or no distress. Throughout these years there was considerable gagging and choking. There were also frequent coughing spells and occasional bringing up of food particles. The patient had lost 18 to 20 pounds in weight and felt weak and tired. During these 10 years the patient had four attacks of pneumonia, the first episode occurring 8 years previously. Six years previously, she had a diffuse bronchopneumonia, at which time her life was despaired of,

and ran a febrile course for at least 6 weeks; careful bacteriologic studies revealed no pneumococci in the sputum or the blood. Another attack of pneumonia, relatively mild in character, occurred 4 years previously. The last attack occurred 2 years previously, when the patient was again seriously ill for 5 weeks. Following the pneumonia 6 years previously, she developed a polyneuritis that was ascribed to vitamin deficiency, apparently precipitated by the prolonged fever and inability to partake of adequate food. She recovered after vigorous parenteral administration of various preparations of vitamin B. The patient presented herself for the treatment of the dysphagia, which in recent months had become aggravated and was accompanied by frequent regurgitation of undigested food.

Physical examination was essentially negative except for evidence of weight loss and moderate dehydration. Roentgenoscopic and roentgenologic examination revealed a markedly dilated and tortuous esophagus with a typical funnel-shaped subdiaphragmatic portion. No barium was seen to pass into the stomach during this examination. The following day the esophagus was dilated under fluoroscopic control and was found still to contain barium. Following this manipulation, barium was seen to enter the stomach. A complete gastrointestinal roentgen-ray examination 2 days later revealed no other disease within this tract. Roentgen-ray examination of the chest was negative.

Within the next 5 weeks, the patient had further dilatations of the esophagus at weekly intervals. The dysphagia improved markedly. She gained 12 pounds in weight and the gagging and choking while taking food, as well as between meals, disappeared.

DISCUSSION

These cases demonstrate two types of pneumonic involvement secondary to a cardiospasm. The first case represents a chronic pneumonitis with repeated exacerbations, presumably due to repeated insults to the affected lung tissue. In this case the significance of the esophageal symptoms in the evaluation of the illness was overlooked for a period of four months because of the predominance of the pulmonary symptomatology. The second case is characterized by repeated acute pneumonic processes, with long periods of intervening relatively good health. A review of recent current literature reveals only a few similar cases. Hoover⁴ reported a case in which a patient with a chronic pneumonitis, apparently of five years' duration, was cured by esophageal dilatations. Tucker⁵ reported a case of chronic pneumonitis in a thirteen-year-old boy who had cardiospasm. Thomas and Jewett⁶ reported the case of a thirty-two-year-old man who had a greatly dilated esophagus due to cardiospasm and died of bilateral pneumonia. He had been receiving feedings of cream as part of a high-caloric diet. At autopsy, histologic examination showed the pneumonia to be of the type produced experimentally in animals by instilling oil into the lungs. Reports of lung-abscess formation, the result of inspiration of retained food in the esophagus, are more numerous, but neither this condition nor suppurative peribronchitis is discussed here.

The establishment of a causal relation may be difficult in a single case. In fact, it is undoubtedly frequently overlooked or a correct diagnosis is made only in retrospect. Jackson and Jackson¹ consider the demonstration of food residue in the pyriform sinuses an indication of esophageal stenosis in which

verflow into the larynx is a possibility. This sign should be looked for in every case of etiologically obscure pneumonitis. The demonstration of inspiration of barium into the tracheobronchial tree is convincing evidence of a causal relation. The observation that the patient coughs up food particles or, as in one of these cases, ingested tablets, should suggest the possibility of an inspiration pneumonia. Finally, a bronchoscopic examination may elicit important diagnostic evidence.

Since the right bronchus is nearer to the vertical than is the left, foreign bodies enter it more frequently than they do the left bronchus, so that most inhalation pneumonias primarily involve the right lung, but a bilateral involvement occurs in cases of massive inspiration. In such cases rapid exitus is the rule.

Repeated dilatations of the esophagus, which minimize the food retention, are recommended in the prophylaxis of inhalation pneumonia as well as in the treatment of this condition. Between attacks of pneumonia, transthoracic plastic surgery of the esophagus should be considered.

SUMMARY

Two cases of cardiospasm complicated by inhalation pneumonitis are reported. This pneumonitis may be either of the recurrent acute type or of the chronic type with acute exacerbations. The alleviation of the cardiospasm by bouginage improves the general condition and contributes to the cure of the pneumonic process. It is recommended that the esophagus be investigated routinely in all cases of etiologically obscure chronic pneumonitis or recurrent acute pneumonia.

6. Thomas, W. S., and Jewett, C. H. Pneumonia following aspiration of fats from esophagus dilated as result of cardiospasm. *Clifton M. Bull.* 12:150-158, 1926.

Corrections. In the article "Paget's Disease: Its pathologic physiology and the importance of this in the complications arising from fracture and immobilization" by Drs. E. C. Reifstein, Jr., and Fuller Albright, which appeared in the September 7 issue of the *Journal*, two corrections should be made. In the ninth line of the sublegend of Figure 1, the word "hyperplasia" should be "hypoplasia." In the twenty-seventh line of the first column on page 351, the figures "135/195" should be "135/95."

The temperature remained normal from the 64th to the 86th day, when the patient was discharged. She stated that she felt much improved and that she was able to swallow more easily than she had for years. Furthermore, regurgitation of food was almost completely absent. During the hospital stay the patient gained 10 pounds in spite of the two prolonged attacks of aspiration pneumonitis.

Four days after discharge, the patient again began to regurgitate and developed a temperature of 101.4° F., as a result of which she was readmitted. On examination only a few rales could be heard at the lung bases. The temperature returned to normal on the 2nd hospital day with the use of symptomatic therapy only. The patient was kept in the

FIGURE 4. Roentgenogram of Chest (January 19, 1944). This film shows considerable clearing in both lungs, consistent with resolving pneumonia.

hospital for 2 weeks, and throughout this period manifested no more signs of pneumonia and no further fever; regurgitation did not recur.

Three months after the second discharge, the patient was again seen in the Outpatient Department. She was still well and her weight had increased to 108 pounds, a gain of 23 pounds from the lowest weight 4 months previously. Some regurgitation was still present, but swallowing was much easier than it had been in the preceding 4 years. The patient reported that she had no trouble at all in swallowing liquid and semi-solid foods. X-ray examination of the chest still showed some scattered infiltration throughout both lung fields, which was interpreted as due to pulmonary fibrosis. Fluoroscopic and radiographic examination of the esophagus revealed continued improvement, but some retention was still present. During these 3 months, the patient had been completely free of fever and her cough had decreased markedly. Another esophageal bouginage was done.

CASE 2. M. E., a 34-year-old woman, had had a history of dysphagia for 10 years. The amount of discomfort varied from time to time, but she was never completely free of symptoms. The difficulty in swallowing was more marked when she partook of solid food. Liquid and mushy food was swallowed with little or no distress. Throughout these years there was considerable gagging and choking. There were also frequent coughing spells and occasional bringing up of food particles. The patient had lost 18 to 20 pounds in weight and felt weak and tired. During these 10 years the patient had four attacks of pneumonia, the first episode occurring 8 years previously. Six years previously, she had a diffuse bronchopneumonia, at which time her life was despaired of,

and ran a febrile course for at least 6 weeks; careful bacteriologic studies revealed no pneumococci in the sputum or the blood. Another attack of pneumonia, relatively mild in character, occurred 4 years previously. The last attack occurred 2 years previously, when the patient was again seriously ill for 5 weeks. Following the pneumonia 6 years previously, she developed a polyneuritis that was ascribed to vitamin deficiency, apparently precipitated by the prolonged fever and inability to partake of adequate food. She recovered after vigorous parenteral administration of various preparations of vitamin B. The patient presented herself for the treatment of the dysphagia, which in recent months had become aggravated and was accompanied by frequent regurgitation of undigested food.

Physical examination was essentially negative except for evidence of weight loss and moderate dehydration. Roentgenoscopic and roentgenologic examination revealed a markedly dilated and tortuous esophagus with a typical funnel-shaped subdiaphragmatic portion. No barium was seen to pass into the stomach during this examination. The following day the esophagus was dilated under fluoroscopic control and was found still to contain barium. Following this manipulation, barium was seen to enter the stomach. A complete gastrointestinal roentgen-ray examination 2 days later revealed no other disease within this tract. Roentgen ray examination of the chest was negative.

Within the next 5 weeks, the patient had further dilatations of the esophagus at weekly intervals. The dysphagia improved markedly. She gained 12 pounds in weight and the gagging and choking while taking food, as well as between meals, disappeared.

DISCUSSION

These cases demonstrate two types of pneumonic involvement secondary to a cardiospasm. The first case represents a chronic pneumonitis with repeated exacerbations, presumably due to repeated insults to the affected lung tissue. In this case the significance of the esophageal symptoms in the evaluation of the illness was overlooked for a period of four months because of the predominance of the pulmonary symptomatology. The second case is characterized by repeated acute pneumonic processes, with long periods of intervening relatively good health. A review of recent current literature reveals only a few similar cases. Hoover⁴ reported a case in which a patient with a chronic pneumonitis, apparently of five years' duration, was cured by esophageal dilatations. Tucker⁵ reported a case of chronic pneumonitis in a thirteen-year-old boy who had cardiospasm. Thomas and Jewett⁶ reported the case of a thirty-two-year-old man who had a greatly dilated esophagus due to cardiospasm and died of bilateral pneumonia. He had been receiving feedings of cream as part of a high-caloric diet. At autopsy, histologic examination showed the pneumonia to be of the type produced experimentally in animals by instilling oil into the lungs. Reports of lung-abscess formation, the result of inspiration of retained food in the esophagus, are more numerous, but neither this condition nor suppurative peribronchitis is discussed here.

The establishment of a causal relation may be difficult in a single case. In fact, it is undoubtedly frequently overlooked or a correct diagnosis is made only in retrospect. Jackson and Jackson¹ consider the demonstration of food residue in the pyriform sinuses an indication of esophageal stenosis in which

chloride, associated with an increase in sodium and bicarbonate. The serum pH was 7.6, and the authors referred to the condition as "an asymptomatic alkalosis of a severe grade." This association of alkalosis and low serum potassium was observed also by Willson, Power and Kepler,⁶³ but in this case tetany was present. Talbot, Butler and MacLachlan⁶⁴ administered methyl testosterone and testosterone propionate to an eight-year-old girl suffering from Addison's disease in an attempt to restore muscular strength, and recorded a striking reduction in serum potassium to 1.9 milliequiv. per liter. They state:

The marked lowering in the serum potassium concentration while the patient was receiving testosterone was not associated with clinical evidence of muscular weakness or paralysis. On the contrary, the patient seemed to benefit from the testosterone, as evidenced by gain in weight, growth in stature and apparent increase in strength and endurance.

They suggest that one of the mechanisms operating in the gain in weight was an increase in intracellular water.

From these observations, and from the experimental evidence that indicates an influence of adrenocortical and associated hormones on the level of serum potassium, Darrow⁶⁵ concludes that deficit of potassium occurs in other clinical conditions, and that unexplained high bicarbonate, low chloride and low potassium in the serum may be the findings that will lead to the discovery of cases. Two subsequent reports bear out his predictions. In a case of Addison's disease in which death occurred in heart failure, histologic changes were seen similar to those found in potassium deficiency.⁶⁶ It was thought that the heart failure resulted from a low serum potassium level, produced by a combination of desoxycorticosterone pellet therapy and a low potassium intake due largely to failure to eat. No potassium determinations were made, however, during the premortal hospitalization, and values during a previous hospital admission were normal. A bibliography of the subject of low potassium is found in this paper and in Darrow's review. Low potassium with an entirely different etiology is reported by Brown, Currens and Marchand.⁶⁷ In their 2 cases there appeared to be an excessive loss of potassium due to renal insufficiency in chronic nephritis, and the serum potassium fell to 2 milliequiv. per liter. The patients complained of extreme muscular weakness, fatigue and paralysis, the T waves in the electrocardiogram were of low voltage and the oral administration of potassium salts appeared to be of benefit.

CURARE

No drug has attracted interest among physiologists equal to that curare has aroused nor proved so useful as a technical tool or as a stimulus to new investigations. Few drugs have had less clinical usefulness. Physiologists are therefore likely to

watch with interest the application of this drug to a variety of purposes for which its unique physiologic properties may prove useful. The most recent and potentially the greatest use is in anesthesia, to secure or to enhance relaxation of skeletal muscle during surgical operations. It was given its first clinical trial in Montreal by Griffith,^{68,69} who has employed it with considerable reservation in situations in which it is impossible or too hazardous to obtain relaxation with the anesthetic agent alone. Cullen⁷⁰ employs the drug more freely, to obtain relaxation rather than to increase the concentration of the anesthetic agent. His practice is to carry the patient in light second-plane inhalation anesthesia and, with proper doses of curare, to obtain relaxation. This is achieved by intravenous injection of at least 0.06 gm. (3 cc.) of the commercial extract (Intocostrin-Squibb), although usually 0.1 gm. is required in the average patient under cyclopropane anesthesia. Ether apparently interferes directly with neuromuscular transmission⁷¹ and requires that the dose of curare be reduced to one third of that used during cyclopropane anesthesia. There is a report that curare has a direct depressant action on the respiratory center,⁷² but the diminution in frequency and depth of respiration noted in an early stage of curarization may represent the reaction of the center to the diminution in reflex drive that must occur as skeletal muscles begin to be paralyzed and fail to set up the reflex stimulus to respiration for which they are normally responsible.⁷³

Curare has also been employed to cushion the convulsions in therapeutic shock,⁷⁴ to prevent the convulsions in tetanus⁷⁵⁻⁷⁷ and as a temporary relief in spastic states.⁷⁸ When employing the drug in these situations, as well as in anesthesia, it is necessary to remember always that the muscles of the respiratory center become paralyzed at very nearly the same level of dosage as do other skeletal muscles, and that it may therefore be necessary to employ artificial respiration. Since with the complete loss of muscle tone caused by the drug the chest has little natural elasticity, chest-pressure methods are ineffective, and those employing positive air pressures must be employed.

DETECTION OF TIME OF OVULATION

Burr, Hill and Allen⁷⁹ noted that an increase occurred in the potential difference between a vaginal and a suprapubic electrode at the time of ovulation in the rabbit, and these findings have been confirmed in other species.⁸⁰⁻⁸⁶ The same phenomenon was shown to occur in women,⁸⁷⁻⁹⁰ and has been advocated as a means of determining the time of ovulation. The cause of the phenomenon has supposedly been electrical potentials developing between the ovary and other organs owing to rupture of the follicle. Study of such potentials in women on whom laparotomies were performed indicated that the potential changes might develop before

POTASSIUM POISONING IN MAN

In 1915, Smillie⁴⁷ reported a temporary episode of collapse with vomiting following the administration of 10 gm. of potassium chloride to a patient suffering from chronic nephritis with uremia. He called attention to the greatly increased toxicity of potassium salts when excretion in the urine was prevented by damage or extirpation of the kidneys in experimental animals. On the basis of these observations he suggested that spontaneous auto-intoxication by the potassium salts liberated in cell metabolism might occur in man if renal elimination of potassium were interrupted. This hypothesis became susceptible of proof through the work of Winkler and his co-workers,⁴⁸ who demonstrated a characteristic series of electrocardiographic changes occurring when experimental animals were poisoned with potassium administered intravenously, and who also showed that this sequence of electrocardiographic changes took place as successively higher levels of serum potassium were attained. In the absence of renal excretion of potassium, poisoning by means of orally administered potassium became possible,⁴⁹ and animals in which the kidneys were removed or the ureters tied invariably succumbed to autointoxication.⁵⁰

Reports are now at hand indicating that an identical situation may develop in man. The first of these comes by coincidence from the Medical Clinic of the Peter Bent Brigham Hospital,⁵¹ where Smillie's original observations were made. It concerns 2 patients with marked oliguria who were given potassium chloride by mouth as a therapeutic measure. In both patients electrocardiographic changes developed that were in every way similar to those shown by dogs in the course of potassium poisoning, and the level of serum potassium at death, examined in one of the patients, agreed with that found in the dog. The same authors⁵² have now reported 2 cases in which potassium poisoning occurred spontaneously, without the administration of potassium salts. Three additional cases have been presented by Keith, Burchell and Baggenstoss⁵³ in which the accumulation of potassium occurred in uremia due to kidney disease.

In accord with a suggestion in an earlier progress report in this series,⁵⁴ it is now reported that in the anuria associated with the crush syndrome potassium intoxication may be responsible for death. Bywaters⁵⁵ reports as follows:

Two thirds of the patients die toward the end of the first week, the majority on the sixth day. Death occurs very suddenly and may be preceded by cardiac irregularity. If electrocardiographic tracings are taken, changes similar to those seen in human potassium poisoning are seen—increased T waves and widened QRS complexes. These are associated with an increase of the potassium level in the serum to more than twice the normal upper level of 20 mg. per 100 cc. The raised serum potassium concentration in crushing injury is due to two processes: first, the muscle potassium diffuses out into the blood stream, its concentration falling from 300 to 70 mg. per 100 cc. or lower, both in man and in animals; secondly, very little of this is excreted owing to renal failure, and thus it accumulates in the body.

In these descriptions of fatal poisoning in man, the maintenance of blood pressure and consciousness until the onset of cardiac arrest is a striking feature, and suggests the value of electrocardiographic examination of anuric and oliguric patients. Marchand and Finch⁵² mention temporary success in restoring the normal heart beat with calcium salts, and Bywaters⁵⁵ suggests the use of glucose and insulin, based on the observation (Fenn⁵⁶) that potassium may be withdrawn from the circulation and deposited in the liver when glucose is laid down as glycogen.

The possibility of another type of potassium poisoning is suggested by the observation of an extremely high blood potassium value (287 mg. per 100 cc.) found post mortem in a woman succumbing to the effects of a soft-soap paste inserted into the uterus to produce an abortion.⁵⁷ The blood cells were completely hemolyzed, and the supposition is expressed that the potassium normally contained in the red cells was released by the hemolysis and raised the effective serum concentration to a lethal level. It is apparent, also, that although fatal potassium poisoning is not a frequent mode of death in experimental traumatic shock or adrenal insufficiency, it occasionally occurs in both of these conditions when survival is prolonged in the presence of oliguria.⁵⁸⁻⁶⁰

Circumstances in which the serum potassium level is abnormally low will probably prove to be more frequent and of greater clinical significance than those in which it is elevated. Familial periodic paralysis is the first well-recognized example. Occasional reports indicate that Cushing's disease may be another. Walters, Wilder and Kepler⁶¹ reported a case that was successfully treated by subtotal resection of the adrenal glands, in which low pre-operative levels (10.4 and 9.3 mg. per 100 cc.) rose to the upper limits of normal (24.6 and 25.5 mg.) after operation. McQuarrie, Johnson and Ziegler⁶² noted a marked reduction in serum potassium and

THE NEURONE THEORY

A review by Nonidez¹¹¹ of the present status of the neurone theory reminds physiologists of the extent which the present structure of neurophysiology is dependent on and associated with the neurone theory. His summary is quoted in full as an admirable account of the recent history of the neurone theory:

During the last decade certain authors have considered the classical neurone theory to be obsolete and have resuscitated the long-rejected hypothesis of a nervous syncytium, mainly on histological evidence. Bauer believes in connexions between embryonic neuroblasts, serving as pathways for the growth of nerve fibers which thus develop intraplastically. This concept must be regarded as entirely hypothetical. Anastomoses found between neuroblasts and nerve fibers growing in tissue culture are emphasized by the reticularists, but this is not overwhelmingly against the neurone theory, since such anastomoses are by no means universal and they depend on the part of the nervous system cultured and on the properties of the medium. Claims by Bauer on the continuity of nerve cells with each other and with neuroglia disagree with the demonstrated existence of free dendrites and of synapses with neurones. Reticularists also maintain the continuity of neurones in the autonomic system, but this too is open to criticism on histological grounds. Moreover, autonomic ganglia afford good material for the demonstration of synaptic endings both in fixed and living preparations. The reality of independent neurones is confirmed by the degeneration of synaptic boutons in the central nervous system after the destruction of nerve tracts, and by the degeneration and regeneration of preganglionic fibers in autonomic ganglia, in which the loss and recovery of function are confirmed experimentally. The existence of the synapses is confirmed by the decay in impulse transmission, varying with the type of synapse, and by the nicotine block to impulses from preganglionic fibers to autonomic ganglia. The recent criticisms of the neurone theory are based on preparations made exclusively by the Bielschowsky technique, unsupported by experimental work, and the several workers disagree widely in their evidence. Boeke claims that the finer divisions of the autonomic system contain a meshwork of neurofibrils clearly distinguishable from the surrounding connective tissue; this structure is not found, however, with other neurofibrillar methods but appears with silver carbonate, which does not stain nervous structures. Stöhr believes in a fine terminal reticulum of the autonomic and sensory systems surrounding every cell in the body. Again other competent histologists, working with techniques which do not stain connective tissue, have failed to confirm Stöhr, whose claims are moreover unsupported experimentally. The reticularists cannot agree among themselves on their substitute for the neurone theory, and it would seem wise to retain this concept until better proof is offered of the syncytial nature of the nervous system.

ORIGIN OF HEART BEAT

The cause of the heart beat presents perhaps the oldest and most controversial problem in physiology; a great part of it is now of historical interest only.^{112, 113} So far as the vertebrate heart is concerned, the long disputes between adherents of the neurogenic and myogenic theories may be said to have resulted in the complete victory of the latter doctrine. However this may be, recent evidence indicates that in acting as pacemaker to the heart the muscular tissue of the sinus venosus or sino-auricular node behaves very much as does a nerve fiber, nerve cell, sense organ or even skeletal muscle in certain circumstances.

With the discovery of the refractory period in the heart,¹¹⁴ it became possible to construct the first rational theory of the origin of the heart beat, as due to the presence of a constant inner stimulus, which set up a beat whenever the heart recovered sufficiently from the refractoriness caused by the previous discharge. This simple explanation appears to account for the repetitive firing of a nerve fiber injured at one end, the local injury current acting as the constant stimulus. In the nerve cell this explanation proved inadequate to account for the relatively slow rhythms exhibited by such neurones as the soleus motoneurone, in which the interval between beats is many times the known absolutely refractory period. With the recognition of the subnormal period, this problem was solved, for it was realized that the motoneurone may show a depression of irritability long outlasting the absolutely refractory period, and that discharge can only occur at the end of this period, when the threshold falls toward normal.¹¹⁵ In the heart even this extension of theory proves inadequate, because it has been repeatedly found that a gradually falling threshold is only occasionally seen, and that usually the threshold remains level for some time before a new beat occurs. This is particularly true of the pacemaker itself, where, in fact, a period of supernormal recovery is at times found.¹¹⁶ This obviously indicates that the inner stimulus of the heart cannot be constant in intensity but is intermittent. This is now established in the vertebrate heart through the work of Bozler,¹¹⁷⁻¹¹⁹ who has studied electric potentials in pacemakers in the smooth muscle of the ureter and small intestine, and in turtle, dog, cat and guinea-pig heart muscle. Apparently pacemaker activity is the result of the spontaneous development of slow rhythmic oscillations of potential, which are found only in pacemaking tissue. These potentials are closely allied to rhythmic oscillations between the negative and positive after-potentials, and if they are sufficiently intense, — about one fiftieth of the normal spike potential, — propagated discharges are set up at their negative crests. These spontaneous, slow, potential changes — so-called "prepotentials" — are apparently the direct cause of the heart beat. They may be increased, or even developed in the heart, by anodal polarization,¹²⁰ and in nerve and skeletal muscle their appearance is facilitated by low calcium and alkalinity.¹²¹⁻¹²³ Although the point has not been settled, it is possible that the so-called "pre-sinus" waves noted by Rijlant¹²⁴ represent prepotentials in the mammalian pacemaker.

ovulation occurred, leading to an extensive study of the problem, which has been published recently.^{91,92} The most crucial observations in this study consist in the failure to detect any potential differences between any two organs in the abdominal cavity greater than about 1 millivolt in 3 women during the course of routine laparotomies performed during the calculated ovulation time. Several follicular surfaces, including that of one fairly large, presumably mature follicle, as well as the intervening ovarian cortex, were tested, but no significant electrical potential was detected. It being concluded that the potentials measured were therefore restricted to the surface, the influence of temperature differences between recording skin surfaces was investigated, and was found to be of the average of 1 millivolt per degree Centigrade in finger-to-finger potentials. The temperature difference between vagina and various skin reference points was also found to be related to vagina-to-skin potentials. Changes in the pH of the skin were seen to affect the potentials recorded between the skin and the vagina. From these studies the conclusion was drawn that "so-called ovulation potentials previously reported, whether elicited between a vaginal and a suprapubic electrode, between two surface areas — abdominal or flank — or between fingers, are measurements only of local changes in peripheral cutaneous blood flow, owing to alterations in capillary tone." Experimental data and calculations indicate that the potential shifts may be occasioned by pH alterations induced by temperature changes.

Although these experiments render it highly unlikely that the so-called "ovulation potentials" arise directly in the ovary as the result of ovulation, they do not detract from the evidence hitherto adduced that they are indeed closely associated with ovulation in time. They do suggest that the method is possibly only a roundabout method of detecting changes in temperature associated with ovulation. Indeed, there is a recurring interest in the use of basal temperature graphs in determining the data of ovulation.⁹³⁻⁹⁷ Tompkins⁹³ reports as follows:

A record of body temperature taken daily under standard conditions shows a typical curve during the menstrual cycle. The temperature is relatively low during the first part of the month, drops to a minimum about the time that ovulation occurs and rises definitely thereafter to a relatively high level, which is maintained until the next menses, when the temperature drops abruptly. Before the menarche, after the menopause and in men, similar temperature fluctuations are not found. If conception occurs, the temperature will remain at the high postovulation level. The important feature is the rapid rise in temperature at ovulation.

Certain evidence in favor of this method comes from Greulich and Morris,⁹⁸ who recorded morning rectal temperatures daily during successive cycles in 14 women aged fifteen to thirty-nine years. In all of them laparotomies were performed and the ovaries were inspected. Eight women showing a characteris-

tic postovulatory temperature rise preceding the operation were found in fact to have ovulated. Five women showed no rise in temperature before operation and were found not to have ovulated. In 1 case a slight rise in temperature began before operation, and sections from the ovary suggested that ovulation was about to take place. This of course fits in with the observation that ovulation potentials may be seen before ovulation begins.^{89,90} In the belief that the temperature changes taking place during ovulation are more marked in the uterus, Klawns⁹⁹ has devised a thermometer by which uterine temperatures may be taken. The evidence he presents does not appear to indicate any decided advantages for this method.

BRITISH AND AMERICAN HEMOGLOBIN STANDARDS

For a number of years a discrepancy has been noted in the hemoglobin standards of England and of America. The English standard was that of Haldane, and was based on the color of carbon monoxide hemoglobin. According to this standard the blood of the average man contains 13.8 gm. of hemoglobin per 100 cc. and has an oxygen capacity of 18.5 cc. American workers, using other methods for determination of oxygen capacity and hemoglobin,⁹⁹ found considerably higher values, namely, 15.8 gm. of hemoglobin and 20.9 cc. of oxygen per 100 cc.¹⁰⁰⁻¹⁰² The discrepancy was at one time attributed to the greater number of automobiles in the United States, which produced a mild degree of chronic carbon monoxide poisoning, with a resultant increase in hemoglobin.¹⁰³ Little support was found for these suggestions, and it was found that, when the Van Slyke method for determining oxygen content was employed, English blood samples showed higher hemoglobin levels than were given by the Haldane hemoglobinometer¹⁰⁴ and that high values could be obtained in other centers of population, such as Sydney.¹⁰⁵ With the arrival in England of American soldiers, it became apparent that there was no difference between the hemoglobin levels in the blood of English and American soldiers, and the reputed differences must have a methodologic origin. When the Haldane standard was re-examined by a new method for assay of hemoglobin,¹⁰⁶ it was found that in fact it corresponded to a hemoglobin content of 14.8 gm. and an oxygen capacity of 19.8 cc. per 100 cc.¹⁰⁷⁻¹¹⁰ "How it has come about," state one group of workers,¹¹⁰ "that this standard, which has been checked and rechecked for more than forty years, could have changed from an original equivalence of 18.5 ml. of oxygen to the present 19.8 ml. is a perplexing problem." They incline, however, to the belief that the fault lies primarily in the reliability of the Haldane method for gas analysis in blood. Whatever the cause, the English standard is now brought more closely in alignment with the American figures.

CASE 30411

PRESENTATION OF CASE

First admission. A fifty-nine-year-old executive entered the hospital for study.

The patient had been in fairly good health until three weeks before entry, when he experienced sudden, severe, generalized and persistent pain in the abdomen. There was no nausea or vomiting, changes in the number, the character or the color of the stools. The pain was unrelated to meals and lasted for nine days. It was relieved by warmth and aggravated by lying down. He had had no recurrence of the pain, no weight loss and no anorexia or night sweats.

He had been asymptomatic until four years before admission, when, because of pain on swallowing, he had had x-ray studies, which showed an esophageal hernia and diverticulum." Twenty years before entry, after a nine-month period of pain, a "duodenal ulcer" was demonstrated by x-ray. Since then he had experienced some subcostal distress after meals, especially after drinking alcoholic beverages and during episodes of nervousness.

Physical examination showed a well-developed, well-nourished man in no distress. The heart and lungs were normal. The abdomen was slightly distended, with slight tenderness in both flanks. The blood pressure was 130 systolic, 80 diastolic. His temperature, pulse and respirations were normal.

Examination of the blood showed a hemoglobin of 14 gm. The white-cell count was 12,200, with 9 per cent neutrophils. The urine was normal. The blood Hinton test was negative. One stool examination was negative. A phenolsulfonephthalein test, intravenous pyelograms and a barium enema were normal. A gastrointestinal series showed a moderate-sized hiatus hernia that emptied freely into the subdiaphragmatic part of the stomach. The stomach itself was otherwise negative. The duodenal cap showed a constant deformity, but no evidence of an active ulcer. A six-hour film showed the stomach completely empty; the head

of the meal was in the colon. He was discharged on the fourth hospital day.

Second admission (one year later). Following discharge the patient had occasional bouts of epigastric distress, characterized as dull, aching and heavy. These were associated with a constant dull pain in the right shoulder. There were occasional periods when he was unable to swallow. He had had no nausea, vomiting or loss of weight. About three months before re-entry the epigastric pain became more frequent and increased in severity. He experienced pain in the left shoulder similar to that on the right. He had had some constipation.

Physical examination showed a well-developed, fairly well-nourished man in no discomfort. The heart and lungs were normal. There was tenderness on deep palpation immediately under the xiphoid, but not elsewhere.

The blood pressure was 120 systolic, 70 diastolic. The temperature, pulse and respirations were normal.

Examination of the blood showed a red-cell count of 4,610,000, with 14 gm. of hemoglobin. The white-cell count was 7200. The urine was essentially negative. A gastrointestinal series showed no remarkable change in the hiatus hernia itself, but there was a constant area of narrowing just above the hernia. Barium passed through this region without much hesitation, but the area did not distend so completely as did the rest of the esophagus. The lumen was somewhat irregular in its course. The stomach was essentially negative. The duodenum showed evidence of an old ulcer deformity. On the first hospital day he had an attack of sharp epigastric pain lasting three hours. An electrocardiogram on the next day was normal.

On the third hospital day an operation was performed.

DIFFERENTIAL DIAGNOSIS

DR. CHESTER M. JONES: The pain that this man complained of was fairly characteristic of ulcer.

There are a lot of facts that are absent here and a lot of definite evidence that can be verified by looking at the series of x-ray films. There is no doubt that this man had a para-esophageal hernia. His symptoms were characteristic of it, although usually the pain of hiatus hernia is substernal rather than epigastric. It appears, however, that he had high epigastric and subxiphoid pain and occasionally pain in the right and left shoulders. If we take these statements alone, knowing that he had a para-esophageal hernia, the picture is entirely consistent. Of course a large number of patients with such a hernia have no symptoms. The fact that the pain went through to the back and radiated at times to one or the other shoulder and arm is also characteristic of many hernias.

is fairly uncommon to find a combination of cancer and ulcer, and a hiatus hernia in addition even rarer. Because of the pain it was probably a benign lesion, since most esophageal cancers are not painful, and there is usually trouble with swallowing, described as a difficulty in getting food by a narrow spot. We must be prepared to be told that there was a carcinoma instead of a benign lesion, but I shall vote for a benign lesion, with partial stricture of the esophagus above the hernia. I still think he should have been esophagoscoped before operation, if it was possible.

DR. CASTLEMAN: Will you describe your operative procedure, Dr. Sweet?

DR. SWEET: First, I should like to comment about esophageal pain in these lesions, particularly the pain of cancer. Many of these patients do have a steady boring pain in the back, which usually is a sign of inoperability. In other words, transmission of pain almost never occurs until there is inflammatory fixation or invasion by the tumor. I am guided by that and by a persistent elevation of temperature in deciding whether a case is operable.

DR. JONES: This patient did not have fever or constant pain.

DR. SWEET: No; but he had a marked change in the character of the pain between the two admissions. I do not know whether or not that is brought out in the abstract. At the time of the first admission the pain was consistent with that of a hiatus hernia. Later, he had the pain of obstruction, and at operation it was quite obvious that he had an annular thickened mass in the lower portion of the esophagus. He had a hiatus hernia, as well as a short esophagus; in fact, he was one of the relatively few patients with a really short esophagus. The mass in the lower esophagus was adherent to the surrounding tissues and looked and behaved grossly like a carcinoma. I thought when I was removing it that I probably was taking out a carcinoma.

CLINICAL DIAGNOSIS

Esophageal (diaphragmatic) hernia.
Carcinoma or ulcer of esophagus?

DR. JONES'S DIAGNOSES

Hiatus hernia with short esophagus.
Peptic ulceration in esophagus or hernia.

ANATOMICAL DIAGNOSES

Hiatus hernia with short esophagus.
Peptic ulcer of esophagus.

PATHOLOGICAL DISCUSSION

DR. CASTLEMAN: The specimen we received was composed of the lower portion of the esophagus and a small portion of the stomach. With the aid

of Dr. Sweet we were able to delimit the part of the specimen that was above the diaphragm and that which was below. Everything below the diaphragm comprised normal stomach. In the center of the portion above the diaphragm was a large ulceration, surrounded by islands of mucosa that proved histologically to be gastric epithelium. We cut four or five sections at various levels, and even in the most proximal section we found a few small islands of stomach epithelium and a few of esophageal epithelium. Microscopically the ulcer had a fibrinoid base characteristic of peptic ulcer.

This case brings up the old question whether the presence of gastric epithelium above the diaphragm means a short esophagus with a portion of normal stomach below it, or whether the gastric epithelium is merely ectopic within an esophagus of normal length. The presence of this amount of gastric epithelium high in the esophagus certainly favors the short-esophagus theory.

The peptic ulceration was undoubtedly caused by the action of the hydrochloric acid secreted by the gastric epithelium on the adjacent epithelium, either gastric or esophageal, or both. I do not see how we can decide the point because we cannot tell what type of epithelium it was before it was ulcerated. My hunch is that both were ulcerated. There was no evidence of carcinoma.

DR. SWEET: This case is extremely instructive. The increasing possibility of the surgical management of lesions in this region of the body brings to my mind the analogy between this lesion and a prepyloric ulcer. I believe that both should be handled clinically in exactly the same way. In other words, I could not tell preoperatively or at the time of operation whether I was dealing with carcinoma or a benign ulcer. The same thing holds true in a prepyloric lesion. Both should be regarded with great suspicion. These esophageal lesions should be resected, because the operative mortality is now down to a perfectly reasonable level, comparable to that of gastric surgery through the abdominal approach.

DR. JONES: Furthermore, it is also true that even if they do not carry so high an incidence of carcinoma as do the prepyloric ulcers, lesions like this are bound to give stenosis before long.

DR. CASTLEMAN: I have been under the impression that most peptic ulcers of the esophagus heal without stenosis. Do you know, Dr. Holmes?

DR. HOLMES: We see so few that I do not know.

I should like to add that this case has brought out an interesting problem in connection with radiology of that part of the body. I have a suspicion that the congenital short esophagus is much more frequent than we had thought it was. I assume that those with the short esophagus are likelier to have regurgitation of food or gastric

I am not at all certain about the diverticulum; it is described clearly at first but is not mentioned on subsequent x-ray examinations. If he had one, it was at the cardiac end of the esophagus. Diverticula may or may not be asymptomatic. One might add that in an esophageal hernia that gives symptoms the esophagus usually shows either local change in the lower end or a true gastritis in the hiatus hernia. In many cases it is worth while to do gastroscopy and esophagoscopy to localize the site of the irritating process.

This man had an ulcer demonstrated by x-ray twenty years before admission. The x-ray films that were taken a year ago and the current ones do not mention ulcer activity in the sense that a crater was visualized. The story as given here is not that of active ulcer unless we say that the last episode—the sharp attack of epigastric pain and so forth—meant a perforation; and then we are at a loss because we know nothing about the physical examination at the time of the last admission. We do not know whether he had epigastric spasm and local tenderness, and there is no information about the episode that led to operation. It is fair to assume that because operation was done on the third hospital day it was thought that he had not a cardiac but a gastrointestinal lesion as the cause of pain. Surgical intervention would be warranted for two or three reasons. One would be an acute perforated ulcer either in the duodenal cap, where it had been localized before, or in the esophagus, just above the herniation or in the herniation itself. An esophageal ulcer is relatively rare. He might have had an incarcerated hiatus hernia that required surgery but this is also an uncommon occurrence, and one would not expect it with a hernia of this size that emptied on both occasions by x-ray. I do not believe that such was the reason for surgical interference. The third reason, which might have had nothing to do with the sharp attack of epigastric pain, is narrowing at the lower end of the esophagus. This suggests intrinsic disease of the lower esophagus due to an inflammatory process around an ulcer or a carcinoma without many symptoms to call attention to it.

At this point I think it would be worth while to go over all the x-ray films to see if anything more can be made out of them, remembering that the surgeon rarely operates on hiatus hernia and esophageal ulcer and also that the clinical picture given is not that of an acute perforation of a duodenal ulcer.

DR. GEORGE W. HOLMES: I have no films to show the diverticulum of the esophagus.

DR. JONES: And it was not mentioned in the fluoroscopic note?

DR. HOLMES: If you do not mind, we shall forget about it.

DR. JONES: I should like to because I do not believe that a diverticulum was present.

DR. HOLMES: This film represents the examination of the colon and is essentially negative. I have been through the films taken of the duodenum; there is a deformity but at no time were we able to demonstrate a crater, and there is nothing in the films to suggest hyperperistalsis. It seems unlikely that the finding was due to an acute duodenal ulcer. The lesion that seems to me to be the most significant is the hiatus hernia, with the esophagus coming in at its top. That is of some importance because it is in these cases of so-called "short esophagus" that ulcerations in the esophagus are likely to occur.

Then we have the films that show the actual lesion in the esophagus. There is a defect that looks like an ulcer crater. I remember this case, and I think that that was interpreted as a benign ulcer of the esophagus.

DR. JONES: In other words, this is not the usual case of para-esophageal hernia but represents the smaller group of cases with a short esophagus. The symptoms can be entirely explained by what we see in the x-ray films. The patient had a hernia and there was a lesion above it in the anterior portion of the esophagus, which was due to inflammatory disease or to an infiltrating process. This is the sort of case that should be esophagoscopy before any surgery is attempted. Was an esophagoscopy done?

DR. BENJAMIN CASTLEMAN: No.

DR. JONES: It may have been impossible because of the emergency that arose on the third hospital day,—the three-hour attack of sharp epigastric pain,—and the surgeons may have thought that it was wiser to operate than to try to establish a diagnosis. A diagnosis could probably have been established by careful esophagoscopy.

I should like to ask what the belly was like after this episode of pain. Was there anything to suggest a perforated ulcer?

DR. CASTLEMAN: Dr. Sweet, can you answer that?

DR. RICHARD H. SWEET: No; I did not see the patient during that attack of pain. When he came in the second time he was having pain, but it was not that of peritoneal irritation.

DR. JONES: That statement modifies the picture. The record states that there was an attack of pain lasting three hours on the day of admission, which may be a little misleading.

DR. SWEET: The pain was induced by eating, and it was rather constant.

DR. JONES: I do not believe that the duodenal ulcer had anything to do with the picture, nor do I believe that the patient had a perforation that warranted surgical interference. The acute or subacute portion of the story probably represents pain arising from an active ulcerated lesion above the hiatus hernia. I do not know whether it was due to cancer or to a peptic ulcer of the esophagus.

DIFFERENTIAL DIAGNOSIS

DR. FLETCHER H. COLBY: In the first admission there is a long history of pain in the lower abdomen and of backache, with a hospital admission in which the essential findings were fever, leukocytosis, lower abdominal tenderness and evidence of peritoneal irritation. At that time a mass was felt in the left side of the pelvis and there was evidence of inflammation of the glands of Skene and Bartholin. With bed rest, intravenous fluids and chemotherapy this acute illness subsided. A reasonable explanation for this episode seems to be an acute flare-up of a pelvic inflammation.

In about two months the patient returned to the hospital with pain and tenderness in the lower abdomen, and what I should suppose was a recurrence of the low-grade pelvic inflammatory process. At that time there was no fever or leukocytosis, and there was but little abdominal tenderness. There were, however, costovertebral tenderness on the left and hematuria. I assume that the hematuria was total, and that the urine was grossly red.

DR. RONALD C. SNIFFEN: Yes.

DR. COLBY: Considerable blood was present in a catheterized specimen of urine. The previous urine was acid, with a low specific gravity and a few pus cells. Evidence that was obtained by cystoscopic, x-ray and pyelographic examinations strongly suggests that the left kidney was the source of the bleeding. At least no note was made of a tumor in the bladder or of any acute inflammatory process of such magnitude as to result in obvious bleeding. Gross bleeding in the urinary tract in the majority of cases — at least 70 per cent — is due to stone, tumor or tuberculosis; in approximately 25 per cent it is due to nontuberculous inflammatory lesions, and in the other odd 5 per cent it is caused by various blood dyscrasias and so forth. So I think that we can fairly assume that this woman had a process in the left kidney that was one of the first three possibilities.

Is there any way of connecting the previous entry with the second entry and the left renal lesion? She might have had a tuberculous pelvic inflammatory process all the time, and it is possible that the left kidney was the site of a primary tuberculous lesion that gave a filling defect. Such lesions are the rare tuberculomas that are found sometimes in the kidney and occasionally in the bladder. It hardly seems likely that this woman had tuberculosis because of the lack of persistent severe bladder symptoms and the lack of any described bladder or vesical changes on cystoscopic examination. So it seems reasonably certain that the pelvic inflammatory disease and the renal disease were two separate things. The diagnosis of the lesion in the left kidney depends entirely on the interpretation of the pyelogram.

DR. MILFORD SCHULZ: This is the film made thirty minutes after the intravenous injection of the dye. You can see the large right kidney and the large left kidney, which has only a little dye in the calyces. This is the shadow thought to be a stone, but on the retrograde pyelogram it is shown to be outside the ureter. The upper calyces are not greatly dilated, but there is a mass projecting from the lateral margin of the left kidney that can almost be traced around the defect in the pelvis and that deforms the middle and lower calyces.

DR. COLBY: Will you look at this flat film and tell me if there is any irregularity of the renal outline.

DR. SCHULZ: Yes; on the left side. You can see it here on the retrograde film. I do not see any evidence of metastases in the bones.

DR. COLBY: The filling defect in the lower end of this kidney seems to be the important sign.

What are the possibilities? In the first place, it might have been a nonopaque stone; in the second place, a tumor of some sort — neoplasm or a blood clot. Nonopaque stone is a difficult diagnosis to make. Air pyelograms are helpful in the majority of cases, as in those of uric acid stone, but at times one cannot diagnose a stone by any means we have of visualization of the interior of the kidney. There is no evidence of calcification in the plain film in this region, and the patient's history somehow does not suggest the presence of nonopaque calculus. Renal pain had not been severe or significant in the history. It was an acute episode accompanied by profuse gross hematuria.

This story suggests a malignant tumor of the left kidney. There are two varieties of tumors — those that arise from the parenchyma and those that arise from the renal pelvis. If we say that it was a neoplasm involving the left kidney, which one was it? My experience with tumors primary in the renal pelvis has been that they involve the pelvis, and the pelvis in this case does not seem to have been involved. I have never seen a primary tumor of the pelvis of the kidney involve a localized area, such as one calyx, but I suppose that it is possible. Against that is the lack of function of this kidney. Function as a general thing was poor from the left kidney, which suggests, not a localized tumor of the renal pelvis, but a tumor involving the parenchyma. Such tumors, as a rule, are renal-cell carcinomas.

DR. OLIVER B. COPE: You exclude an infection, such as tuberculosis?

DR. COLBY: There is no report of a culture.

DR. COPE: What about the x-ray findings?

DR. COLBY: I have to take the evidence that is given.

DR. FULLER ALBRIGHT: Could it have been a polycystic kidney?

juice into the esophagus. We know that ulcer frequently occurs in cases of hiatus hernia with a short esophagus, and we should look more carefully for small esophageal ulcers in these cases. I have seen a number of cases in which the esophagus immediately above the hernia looked narrowed but I have not studied this area with sufficient care. I believe that we are going to be in a position to make better diagnoses in this group. It would be interesting to review the cases in which the patients have had pain to see what type of hernia they had and also to see how many had an ulcer in the esophagus.

CASE 30412

PRESENTATION OF CASE

First admission. A thirty-eight-year-old housewife entered the hospital because of acute epigastric pain.

For about eighteen years, that is, since the birth of her first child, the patient had recurrent attacks of "burning pain and a heavy feeling" in the lower abdomen associated with soreness in the lower back. She had had occasional dysuria, but no nausea, vomiting, fever or chills. The pain gradually increased in severity and frequently occurred while she was in bed. It was increased by coughing, but not by straining, and occasionally preceded menstrual periods. Eighteen months before entry she had an attack of severe, crampy pain in the right upper quadrant, which lasted intermittently for four days. There was considerable vomiting, and frequent headaches. A Graham test was negative. The pain disappeared after four days, but she continued to have gaseous eructations after eating fatty foods. Five days prior to admission the patient began to have severe pain in the lower abdomen and back, which was intermittent until the day before entry, when it became steady. She had dysuria and felt warm, but there had been no chills.

Physical examination showed a well-developed, rather obese woman in some distress. The lungs were clear, but the bases appeared high and the diaphragmatic excursions were limited. The heart was normal. Diffuse tenderness was present over the entire abdomen, most marked in the lower quadrants, where there was rebound tenderness. Peristalsis was normal. Pelvic examination revealed a whitish vaginal discharge. Shotty Skene's and Bartholin's glands were present. The cervix was lacerated and freely movable. One examination revealed a 3-cm. mass in the left vault. There was tenderness in both vaults, more marked on the left.

The blood pressure was 120 systolic, 80 diastolic. The temperature was 102.8°F., the pulse 85, and the respirations 20.

Examination of the blood showed a white count of 11,800. The urine was cloudy, and the sediment contained occasional white cells. A blood Hinton test was negative. A smear of the cervix discharge showed questionable gram-negative cocci but a culture was negative for gonococcus.

The patient was Ochsnerized and given 3000 cc. of 5 per cent dextrose in physiologic saline solution for four days and 6 gm. of sulfadiazine daily for seven days. The pain, tenderness, nausea and vomiting subsided and she was discharged on the eleventh hospital day.

Second admission (about two months later). After discharge she was well for one month, which time the lower abdominal pain and tenderness recurred. There was pain in the left flank and the costovertebral angle, radiating to the suprapubic region and up to the left shoulder. The character of this pain and its relation to the lower abdominal pain were not recorded. Three days before entry she developed persistent hematuria.

Physical examination showed a normal heart and normal lungs. Slight tenderness was elicited on palpation of the abdomen. Tenderness and sense of resistance were present in the left flank but no masses were palpable. Pelvic examination revealed some tenderness but no masses.

The blood pressure was 152 systolic, 94 diastolic. The temperature, pulse and respirations were normal.

Examination of the blood showed a white count of 9000, with 12.8 gm. of hemoglobin. The urine was acid, with a specific gravity of 1.008 and a + test for albumin; the sediment contained 60 white cells, 25 epithelial cells and rare red cells per high-power field. A second (catheterized) specimen contained numerous red cells. The nonprotein nitrogen was 26 mg. per 100 cc.

A plain film of the abdomen showed both kidneys to be large. The left kidney was somewhat lower than the right. There was a small area of calcification 3 cm. below the level of the left sacroiliac region. An intravenous pyelogram revealed prompt excretion of the dye by the right kidney outlining a nondilated pelvis, calyces and ureter. Only an extremely small amount of dye was visible in the region of the calyces of the left kidney and there was no further evidence of dye in 30 minutes. The left ureter was not visualized. The outline of the left pelvis and calyces was so faint that no conclusion could be drawn. Retrograde pyelograms of the left kidney showed the calcified area to be outside the ureter. The left ureter, pelvis and superior calyces filled normally. The lateral branches of the lower calyx were dilated, with loss of normal cupping. In one of the films a filling defect was seen in this calyx. X-ray films of the chest were negative.

On the tenth hospital day an operation was performed.

COMMUNICATIONS should be addressed to the *New England Journal of Medicine*, 8 Fenway, Boston 15, Massachusetts.

TREATMENT OF MENINGOCOCCAL MENINGITIS

In few conditions have the sulfonamide drugs proved of greater value than in certain types of bacterial meningitis, particularly meningococcal meningitis. The case fatality rate of epidemic meningitis was about 40 per cent in Army camps during World War I, in spite of the fact that intensive treatment with antimeningococcus serum was used. During the present war the over-all mortality from this disease in the Army and Navy is well under 5 per cent, and in several large posts 100 or more consecutive cases have been treated with fatality rates of 2 per cent or less. Further-

more, there has been a remarkably low incidence of complications.

These brilliant results have been obtained with a relatively simple treatment—the oral administration of sulfonamide drugs, supplemented when necessary in severe cases by the intravenous injection of their sodium salts.¹ This is in contrast to the traumatic and cumbersome methods formerly used—the intravenous and intrathecal injection of serum. Antimeningococcus serums are still used by some medical officers and civilian physicians, perhaps because they prefer to cling to tradition or because they assume that serum therapy is an essential part of “doing everything possible.” There seems to be little, if any, reason for believing that this supplementary form of therapy is of additional benefit. Indeed, there is increasing evidence that antimeningococcus serum, particularly when given by the intrathecal route, may actually do more harm than good in most drug-treated cases.

The sulfonamides have also been highly effective in the management of meningococcus carriers, particularly the mass elimination of such carriers from large military units. The latter can be accomplished by a single dose or by one short course of a few grams of a sulfonamide drug given orally in a single day and is, likewise, in sharp contrast to the cumbersome, and usually unsuccessful, methods employed during World War I.

Drug-fastness is a serious problem in the sulfonamide treatment of infections with the gonococcus, an organism that is closely related biologically to the meningococcus, and increasing numbers of sulfonamide-resistant cases of gonorrhea are constantly being encountered in all parts of the world where these drugs are widely used. Among the sulfonamide-treated cases of meningococcal meningitis there have been some failures, particularly in fulminating acute cases and in late and neglected ones. There have also been some apparent failures, owing to the improper control of therapy, which vitiated or obscured the beneficial effects of the drug. There have been few, if any, authentic cases, however, in which the sulfonamide resistance

DR. COLBY: It was unilateral; I have never seen a case of unilateral polycystic disease, although they have been reported. In the x-ray films there is nothing to suggest to me that a bite had been taken out by a cyst. The defect is irregular, suggesting a tumor or blood clot.

CLINICAL DIAGNOSIS

Renal tumor.

DR. COLBY'S DIAGNOSIS

Renal-cell carcinoma.

ANATOMICAL DIAGNOSIS

Polycystic kidney.

PATHOLOGICAL DISCUSSION

DR. SNIFFEN: The specimen proved to be a polycystic kidney. It was of normal contour, as most of them are, and about twice the normal size. Externally and internally it was riddled with cysts, so that there was little parenchyma—just two or three islands of recognizable cortical tissue. The pelvis and calyces were dilated, but not greatly distorted. I do not believe that this kidney explains all the patient's symptoms; in all probability the first symptoms were due to pelvic inflammatory disease.

DR. ALBRIGHT: What was the x-ray diagnosis?

DR. SNIFFEN: Neoplasm of the left kidney.

DR. COLBY: And the preoperative diagnosis?

DR. GEORGE G. SMITH: I operated on this patient, and the preoperative diagnosis was renal tumor.

DR. COLBY: That makes me feel better.

DR. SNIFFEN: The cause of death in patients with polycystic kidneys is assumed to be a gradual enlargement of the cysts without increase in num-

ber, with consequent atrophy of the remaining parenchyma. In a few cases, however, there is the added factor of hypertension, following vascular changes in the kidney. In such cases, renal failure can be explained, at least in part, by severe nephrosclerosis.*

DR. LLOYD MILLS: In the absence of more information about the urine, what do you think was the cause of the pain?

DR. SNIFFEN: Several things may cause pain among them hemorrhage into a cyst and clotting of blood in the ureter.

DR. SMITH: A cyst will rupture into the pelvis. I have seen it happen with a solitary cyst, producing hematuria and a filling defect, a picture similar to that in this case.

In my operative note I said that the reason for removing the kidney was that the function was poor. It was obviously polycystic disease at operation. The other kidney was apparently carrying on the work. The blood nonprotein nitrogen was normal, and I thought that the patient would get into further trouble if the kidney were left in.

DR. SNIFFEN: The chances are that there was at least some degree of polycystic disease on the other side.

DR. SMITH: That may be true. On the other hand, a patient from whom I removed a polycystic kidney twenty years ago is still in excellent health.

Years ago we used to have a great deal of argument in the American Urological Association about polycystic disease. One member maintained that polycystic disease was unilateral as frequently as bilateral. A number of cases were discussed.

DR. SNIFFEN: Unilateral polycystic kidney does occur, but such cases are far in the minority.

DR. SMITH: Not over 5 per cent, I should say.

MINIMUM CURRICULUM AND SYLLABUS FOR SCHOOLS OF NURSING

THE Massachusetts Authority for Schools of Nursing has just issued a booklet to guide nursing schools in the construction of their curriculums. In the preface it is explained that this represents the joint effort of representative physicians and nurses to agree on what should be included in the ideal course of nursing. The impossibility of devising an inflexible statement of what should be included and what should be deleted is recognized, and is met by placing an asterisk opposite the subjects that are deemed most important. This, of course, represents a compromise between the thinking of those who wish to elevate the profession of nursing onto higher and more scientific levels and those who wish to extend its practical applications over a wider field of availability and usefulness — two aims that are quite diverse.

The same controversy exists in medical education: there are those who would exalt science and research exclusively and those who think that doctors should be trained merely to care for the sick population. Neither of these attitudes should be permitted to develop to any extreme degree or to the exclusion of the other. It is true that the outstanding individuals in any profession rise by their own innate aptitudes fully as much, or more, than by the schooling to which they are exposed. Without the schooling, on the other hand, they lack the sanction of authority — they are "irregulars," if such a noun is permitted, and there are irregulars in both camps.

The syllabus represents a nice balance between these educational elements. It will undoubtedly be a most useful and much-needed guide to those who are interested in the training of nurses, but it will naturally need periodic revisions and occasionally rewritings. The *Journal* welcomes it as an unusually competent statement concerning an important educational problem.

MISCELLANY

NOTE

The Board of Overseers of Harvard College at their regular meeting on September 25 approved a recommendation of the Faculty of the Harvard Medical School that women students be hereafter eligible for admission to the school. The recommendation had been previously approved by the Harvard Corporation and will become effective for students entering the school in the fall of 1945.

CORRESPONDENCE

BASAL TUBERCULOSIS

To the Editor: It was with great pleasure that I read the article by Dr. Emil Z. Ossen in the June 8 issue of the *Journal*. He treated the subject of basal tuberculosis in a masterful manner because the disease, being as uncommon as it is, often presents an annoying diagnostic problem. I might mention that we have seen a few cases over here that exemplified the material presented by Dr. Ossen.

At present, we have a young soldier of twenty-three who has basal tuberculosis in the upper portion of the left lower lobe. He, of course, will be sent back to the United States shortly. A history of familial contact, the physical findings, x-ray slides and the laboratory evidence are conclusive. When seen on sick call a few days ago, he presented only a few signs of pathology, namely, a low-grade fever (99.5°F.) and a few localized subcrepitant rales below and medial to the lower angle of the scapula. He felt quite well systemically — no lassitude, apathy or weakness. He was somewhat apologetic for coming on sick call. He had no history of anorexia, loss of weight, hemoptysis, night sweats or other evidence of tuberculosis. His history was one of parental exposure fifteen years previously, and none since then. Atypical pneumonia was believed to be the diagnosis when he was admitted to the hospital. Sputum taken immediately to the laboratory proved positive for tubercle bacilli. X-ray films showed a basal lesion, and none in the apex. A cavity was seen in the involved area. I should call this a "pure type." It is a fulminating type, I believe, in view of the lack of prodromal symptoms and the positive sputum. Frankly, I consider this type of tuberculosis somewhat terrifying because I believe that its detection can, at times, be extremely difficult. As mentioned in Dr. Ossen's article, bronchiectasis, neoplastic disease, pulmonary abscess and even mycoses can be ruled out rather easily most of the time. I am not quite so certain about atypical pneumonia, especially if negative sputums are obtained, as they are often at the onset of the disease. Pneumonitis certainly can appear on x-ray examination at a situation similar to that of the earliest stage of basal tuberculosis.

So far as the diagnosis of atypical pneumonia goes, over here we see far more unilateral than bilateral involvement, at least in the severe forms, which are not infrequent. Most of the medical officers here believe that this disease is transmitted from person to person by the usual droplet method, a theory that is not generally accepted by the profession. Furthermore, most of these patients show few physical signs for two or three days, and these usually are a few localized rales and nothing else. X-ray films show a picture similar to that of pneumonitis. Most of the patients stay in the hospital with a low-grade fever for two or three weeks. Treatment, of course, is symptomatic. Atypical pneumonia as seen over here certainly must be ruled out in these cases.

A final word about tuberculosis. I believe that a young person with long-continued fever and minimal pulmonary involvement has a graver prognosis than an older person with extensive involvement but with little fever. This is not exactly my own idea, but it has been impressed upon me during my tenure in the Army.

In conclusion, the matter brings out the old axioms and rules for practicing good medicine — CAREFUL HISTORY, CAREFUL PHYSICAL EXAMINATION, and CAREFUL AND COMPLETE LABORATORY EXAMINATION.

BOOK REVIEWS

The Inner Ear, Including Otoneurology, Otorrhinology, and Problems in Modern Warfare. By Joseph Fischer, M.D., and Louis E. Wolfson, M.D. 8°, cloth, 421 pp., with 77 illustrations and 7 tables. New York: Grune & Stratton, 1943. \$5.75.

This book, considering the senior author's excellent record as a teacher and contributor in this particular subject, fails to accomplish what the aim expressed in the preface — a simplified discussion of the inner ear. The fault does not lie with the contents of the book but mostly in the manner in

of meningococci obtained from human cases was bacteriologically proved.

With the introduction of penicillin and the demonstration of its effectiveness in the treatment of various infections, it was natural to explore its potentialities in all fields. The good results obtained with sulfonamides and the limited supply of penicillin did not permit early and extensive trials of the latter agent in meningococcal infections. Hence, only a small number of cases were included in the first extensive reports covering the clinical use of penicillin. In spite of the small number, it was evident that the results obtained with penicillin in meningococcal meningitis were not dramatic and that failures were encountered, particularly in cases in which sulfonamides had not been used.

Elsewhere in this issue of the *Journal* there is a report of an intensive study of a small group of cases of meningococcal meningitis treated with penicillin alone. The bacteriologic as well as the clinical results in these cases were quite disappointing when compared with those usually obtained with sulfonamides. So far as it is now known, cases of meningitis require intrathecal as well as parenteral treatment with penicillin to control the meningeal infection. This is accompanied by a definite and not insignificant inflammatory reaction, manifested by an increase in the pleocytosis of the spinal fluid and often by exaggeration of the signs and symptoms of meningeal irritation. These reactions are undesirable and often harmful, since they may interfere with the prompt bacteriologic cure and may prolong and aggravate the clinical symptoms. The parenteral and intrathecal use of penicillin, and even its use as a spray, have apparently failed also to rid the nasopharynx of meningococci.

The results in this series of cases were obtained with doses of penicillin that are usually considered to be adequate and in cases in which care had been taken to eliminate any effect of sulfonamides. The authors found out that the latter — that is, the exclusion of sulfonamide therapy — is essential in evaluating the effect of penicillin in cases of meningococcal infection.

Some good results following the use of penicillin in experimental and clinical meningococcal infections have been recently reported. Experimental infections, however, are not comparable to clinical cases of meningitis; moreover, the results were not nearly so good as those obtained in experimental infections with other organisms, such as pneumococci and streptococci. In the clinical cases, as previously stated, the actual role of the penicillin cannot be evaluated unless the effects of sulfonamides are excluded. Unfortunately, this point is not stressed in these reports — for example, that of Rosenberg and Arling.² There, it is stated that the only fatal case in the series did receive a sulfonamide drug. Furthermore, the fact that negative primary cultures and smears of the spinal fluid were obtained in 15 of the 65 cases strongly suggests that a sulfonamide had been given in these 15 cases and perhaps in many of the other cases before the initial dose of penicillin.

For practical purposes it may be said that sulfonamide drugs still constitute the treatment of choice in meningococcal meningitis. Penicillin therapy is more laborious, more traumatic and more expensive, in addition to being less effective in curing the meningeal infection and in eliminating the carrier state. From the information thus far available it seems wise to reserve penicillin for use as an adjunct to the sulfonamide drugs in those cases in which the latter do not bring about an adequate clinical response or for use in cases in which sulfonamide drugs cannot be given. Penicillin may also prove helpful in the management of focal purulent meningococcal infections, particularly those of the joints. Withdrawal of synovial fluid and intra-articular injection of penicillin may hasten the bacteriologic cure of such infections. It is not clear from present reports whether the clinical results of the use of penicillin in such focal complications are superior to those observed with sulfonamides.

Elements of Medical Mycology. By Jacob H. Swartz, M.D. With an introduction by Fred D. Weidman, M.D. 8°, cloth, 9 pp., with 78 illustrations. New York: Grune and Stratton, 1934. \$4.50.

This excellent elementary text, covering the organisms commonly encountered in the United States, fills a distinct void in medical mycology. In the general discussion, the principal morphologic characters are defined and accompanied by line drawings; the commoner genera are listed with the organs usually attacked and the names of the diseases produced. This is followed by a detailed account of the laboratory methods for the confirmation of the clinical diagnosis that the author has found most useful in his practice. The chapter on the yeast-like fungi is largely clinical and therapeutic, with little detail on the organisms involved beyond the information necessary to refer them to this group. The trichophytons producing various tinea are treated in much more detail. Blastomycosis (Gilchrist's disease), coccidioid granuloma, chromomycosis, sporotrichosis, actinomycosis, tinea versicolor and histoplasmosis are grouped in a chapter of miscellaneous organisms, followed by a short chapter on common contaminants. A brief chapter on immune reactions and one on the effects of sulfanilamide and its derivatives, an extensive glossary and a folding chart presenting the salient features of the book in tabular form complete the work.

Although this book may seem oversimplified to the specialist in this field, it should prove a valuable text for the beginner and for the busy clinician. It is unfortunate that the author has placed the organism of Gilchrist's disease among the Blastomyces in violation of the international rules of botanical nomenclature and has confused the clinical pictures of Brazilian blastomycosis caused by *Paracoccidioides brasiliensis* and by *P. cerebriiformis*. The illustrations of lesions are well chosen, and the photomicrographs of the organisms are excellent.

BOOKS RECEIVED

The receipt of the following books is acknowledged, and this listing must be regarded as a sufficient return for the courtesy of the sender. Books that appear to be of particular interest will be reviewed as space permits. Additional information in regard to all listed books will be gladly furnished on request.

Handbook for the Medical Secretary. By Miriam Bredow, dean of women, Eastern School for Physicians' Aides. 8°, cloth, 253 pp., with 18 illustrations. New York: McGraw-Hill Book Company, Incorporated. 1934. \$2.25.

This manual is written for medical secretaries who are already employed and also as a text for students training for the various phases of work to be found in the office of a physician. A valuable vocabulary of approximately 2000 medical terms is appended to the text. Pronunciation is given for the words uncommon to the layman. The vocabulary is divided into subjects, and would be more useful if it had been arranged in one alphabet.

The Permeability of Natural Membranes. By Hugh Davson, D.Sc., associate professor of physiology, Dalhousie University, Halifax, Canada, and James Frederic Danielli, D.Sc., A.I.C., Beit Memorial Research Fellow and Fellow of St. John's College, Cambridge, England. With a foreword by E. Newton Harvey, Ph.D., professor of physiology, Princeton University, 8°, cloth, 361 pp., with 73 illustrations and 72 tables. New York: The Macmillan Company, (Cambridge, England: University Press), 1943. \$4.75.

The authors have brought together in this volume the existing knowledge of cell permeability.

Traumatic Injuries of the Facial Bones: An atlas of treatment. By John B. Erich, D.D.S., M.D., consultant in laryngology, oral and plastic surgery at the Mayo Clinic, and assistant professor of plastic surgery, Mayo Foundation for Medical Education and Research, Graduate School, University of Minnesota; and Louie T. Austin, D.D.S., head of Section on Dental Surgery at the Mayo Clinic, and associate professor of dental surgery, Mayo Foundation for Medical Education and Research, Graduate School, University of Minnesota. In collaboration with Bureau of Medicine and Surgery,

United States Navy. 12°, cloth, 600 pp., with 333 illustrations. Philadelphia and London: W. B. Saunders Company, 1944. \$6.00.

The present war has shown a decided increase in serious facial injuries, the treatment of which is becoming more and more complex. The large experience of the authors at the Mayo Clinic has been drawn on in presenting treatment for the various types of injuries of the facial bones. The major portion of the work is given up to a discussion of fractures of the facial bones. A small portion is devoted to bone and skin grafting, wiring and splinting.

An Atlas of Anatomy. By J. C. Boileau Grant, M.C., M.B., Ch.B., F.R.C.S. (Edin.), professor of anatomy, University of Toronto. Volume II. *Vertebrae and cerebral column, thorax, head and neck.* 4°, cloth, 184 pp., with 232 illustrations. Baltimore: The Williams and Wilkins Company, 1943. \$5.00.

This is the concluding volume of an atlas designed to meet the needs of teachers and students, physicians and surgeons. The regional presentation, which is based on American methods of dissection, makes the atlas of permanent value in clinical work. The illustrations were taken from actual specimens, and the accuracy of the plates was checked by photographic means. The observations and comments that accompany the illustrations are not exhaustive descriptions but are designed to attract attention to salient points that might otherwise escape notice. The color work is good, reminding one of the best German atlases.

Education and Health of the Partially Seeing Child. By Winifred Hathaway. A publication of the National Society for the Prevention of Blindness, Incorporated. 8°, cloth, 216 pp., with 34 illustrations and frontispiece. New York: Columbia University Press, 1943. \$2.50.

This valuable monograph on a sociologic subject is of great importance to the community, since it has to do with the child who is usually a misfit in the public schools. Mrs. Hathaway is an authority on blindness and in this book explains the principles underlying educational procedures and health service for partially seeing children and shows that they may be applied to further the education and health of these children wherever they may live. She describes specifically the equipment, mechanical devices and teaching methods that are available and also discusses the various problems of classification, supervision and financing that are involved in an education program for partially seeing children. The book is designed for all persons, including parents, who are responsible for the partially seeing child. It is interesting to note that the first class in the United States established especially for partially seeing pupils was inaugurated by the Boston School Committee in 1913. This text should serve as an authoritative reference source on its subject.

On the Influence of Trades, Professions and Occupations in the United States in the Production of Disease. By Benjamin W. McCready, M.D. With an introductory essay by Genevieve Miller, M.A. 12°, cloth, 129 pp. Baltimore: The Johns Hopkins Press, 1943. \$1.75.

The text of McCready's prize dissertation, originally published in New York City in 1837, is reproduced in full. In the introduction, Miss Genevieve Miller, assistant at the Institute of the History of Medicine, Johns Hopkins University, comments on the conditions of industry in the United States at the time of McCready's dissertation. She also discusses briefly the life and work of McCready and proceeds to analyze his monograph. In preparing his essay on occupational diseases in America, McCready endeavored to obtain information on the subject by writing letters and interviewing workmen but without much success. He also tried to consult the books of various trade organizations to find material on mortality rates, but again was disappointed since there were no records at all or only imperfect ones. Therefore, with such scanty material he depended rather extensively on a book by Thackeray on occupations, published in London in 1851. He included also personal observations made when he was house physician at the New York Hospital. Miss Miller characterizes the McCready essay as the first American treatise on occupational diseases. Thirty-one types of employment, divided into four sections, are discussed, and in her introduction she points out those details that are additions to the previous literature. She concludes that the essay was a remarkably mature and realistic ap-

which it was printed and illustrated. The illustrations, particularly the photographs of temporal bone and skull, are not well reproduced. The reader therefore misses much of the subject matter because of the lack of comprehensive illustrations. The experienced otologist will enjoy reading the chapters dealing with physiology and anatomy, which are interestingly presented.

There is a definite need for a treatise of this kind for otologists, neuro-otologists and neurosurgeons. In the next edition the authors in all probability will overcome these not too serious defects.

A Clinical and Experimental Investigation of the Blood Cholesterol Content in Myxedema and Other Conditions. By E. H. Stokes, M.B., Ch.M. (Sydney), F.R.A.C.P. 4th, cloth, 121 pp., with 13 illustrations. Sydney: Australasian Medical Publishing Company, Limited, 1941.

The writer of this monograph happened to become interested in cholesterol metabolism through seeing a patient with myxedema and hypercholesterolemia. This was nineteen years ago. Ever since then the riddles of cholesterol metabolism have fascinated him, and in 1928 he began to attempt to solve them by systematic study.

The result of all the work that he has done in this field is now printed. The author writes easily, so that what he says is well expressed. He is a good student of literature, so that he has compiled a useful bibliography. He is conservative in his conclusions, so that he modestly admits there still are many undiscovered factors other than a deficiency of thyroid that may play a part in producing hypercholesterolemia in myxedema.

On the whole this book will prove a useful one for reference. It is especially pleasant to welcome it as a fair sample of the type of medical investigation now going forward in the laboratories and wards of our Australian colleagues.

Strabismus. Its etiology and treatment. By Oscar Wilkinson, M.D., D.Sc. In collaboration with Richard W. Wilkinson, M.D., M.Sc. (med.). Second edition, revised. 8th, cloth, 369 pp., with 71 illustrations. Boston: Meador Publishing Company, 1943. \$4.00.

The second edition of this book, with the chapters on non-surgical and surgical therapy largely rewritten, and with ample recognition and citation of authorities throughout the text, offers an ideal review of the problems in strabismus for the young ophthalmologist.

Adequate attention is given to etiology and types of strabismus, to methods of examination of the patient, and to non-operative and operative therapeutic procedures and their indications. The text is concisely and interestingly written and is amplified by numerous illustrations and drawings. Forty pages are devoted to illustrative cases, with essential items from the case history, and photographs before and after treatment.

Life Is Too Short: An autobiography. By C. Kay-Scott (Frederick Creighton Wellman, M.D.). 8th, cloth, 348 pp. Philadelphia: J. B. Lippincott Company, 1943. \$3.50.

Dr. Frederick Creighton Wellman, also known under the name of C. Kay-Scott, is one of the few people who appears in *Who's Who in America* under both names. He has led a most extraordinary life and his volume of reminiscences is an interesting autobiography of a man of many careers.

His grandfather, a physician born in Virginia, served in the Civil War on the Confederate side. He later moved to Missouri, where the author was born in Independence. His father became a missionary to Indian tribes, and the son always had a desire to become a missionary physician. After graduating from the Kansas City Medical College and serving as an intern in the Kansas City Public Hospital, he went to Central Africa, where he lived for a number of years as the medical officer to an American mission. There he did considerable research in pure science, as well as in medicine, particularly in zoology and entomology. He published an elaborate monograph on the fevers found in Central Africa, as well as several articles on plants and a systematic, annotated check list of insects. He thus was brought

quickly into the scientific world and became well known in England and elsewhere as a student of entomology. Later, he went to California, where he taught at San Francisco, and ultimately to New Orleans.

Following that period of his life, he journeyed to Brazil, gave up the practice of medicine and became a mining engineer. He then turned to the field of literature, wrote novels and began to paint, changing his name to C. Kay-Scott. Thus he began a new career, in which he was eminently successful, for in addition to his painting, which was widely admired, he eventually became director of the Denver Art Museum and dean of the College of Fine Arts at the University of Denver. Ultimately, he was reunited with his family, from which he had been long separated. During his life he was married and divorced a number of times, but it was with the children of his first wife that he finally found himself happily reunited, looking back on an extraordinary career.

This autobiography is somewhat overwritten, but a physician will find much of interest in the book regarding an unusually talented man—physician, missionary, scientist, explorer, mining engineer, novelist and painter.

Internal Medicine in General Practice. By Robert P. McCombs, M.D. 8th, cloth, 694 pp., with 114 illustrations. Philadelphia: W. B. Saunders Company, 1943. \$7.00.

The author has written a classic type of practical textbook in an abbreviated form. He frankly states that he has had to appear dogmatic to achieve brevity, which lessens classroom value, but the book is well and entertainingly written, with more than a modicum of common sense through its pages.

The section on diagnosis follows orthodox lines. It is to be noted that the Hinton test is not included in the serologic tests for syphilis. The chapters on the heart, urinary tract and gastrointestinal tract are unusually complete for so small an edition, the last including a section on gastroscopy. The chapter on nutritional deficiencies is free from fantasy.

The blood dyscrasias are well covered. Infectious diseases are brought up to date, and there is an excellent chapter on the sulfonamide drugs, with an unusual listing of diseases in which the sulfonamides are not indicated. There is a brief note on penicillin. Chronic lung diseases and rheumatic disorders are ably discussed, and there is a chapter on the endocrine disorders. The field of allergy is briefly considered, and neurology and psychiatry are covered by a brief chapter on common neurologic and psychiatric problems.

The book is illustrated with excellent photographs, well-devised diagrams and a number of carefully selected x-ray plates.

The Nature and Treatment of Mental Disorders. By Dom Thomas Verner Moore, O.S.B., Ph.D., M.D. With a foreword by Edward A. Strecker, M.D. 8th, cloth, 312 pp. New York: Grune and Stratton, 1943. \$4.00.

Throughout this book the author maintains a benignly middle-of-the-road course that enables him, without crowding, jostling, or conflict, to salute Kraepelin, Freud, Jung, Adler, psychosomatics, neurology, statistics, commonsense and a number of other things and people of importance in psychiatry. Such benignity is especially becoming to the author as a member of the Order of Saint Benedict.

In his broad empiricism he includes his own psychiatric speculations and conclusions and a summary of investigative work that he himself has conducted and published earlier and elsewhere. Since the book is brief, his presentation of so many topics is certainly in some, and perhaps in most or all, of the cases necessarily superficial.

On the credit side his eclecticism enables him to display a wide range of psychiatric resources and methods—and, incidentally, he shows himself deft and resourceful in their utilization.

Throughout the book, general discussion is amplified by a large number of case histories. These are presented vividly and, as a rule, briefly; and in every case his analysis of therapeutic procedure is clear, and his estimate of therapeutic accomplishments is a model of honesty.

STUDIES IN MEDICAL SOCIOLOGY

I. The Relation of Mental Disorders to the Community Socioeconomic Level

MAJOR ROBERT W. HYDE, M.C., A.U.S., AND SERGEANT LOWELL V. KINGSLEY, A.U.S.

BOSTON

THE purpose of this paper is to show the variations in incidence of mental disorders in the selectees from communities of different socioeconomic levels. No previous study of this type has been made of an unselected cross section of the male population.

Observations derived from rates of admission to mental hospitals have the obvious weakness of failing to eliminate the selective factor involved in hospitalization. They are not based on the examination of a cross section of supposedly normal persons, nor do they have the advantage of disclosing those mild, incipient, arrested or well-compensated disorders that in civil life may never lead to hospitalization. Even so, such studies have indicated that socioeconomic level may be influential in causing or precipitating mental disorders. Thus, Dayton,¹ in a study of admissions to hospitals for the insane in Massachusetts, showed that the most frequent mental disorders in the economically dependent group were mental deficiency and the senile and undiagnosed psychoses, whereas in the economically more fortunate group the involuntional psychoses and those due to drugs were more frequent; among illiterates mental deficiency and senile and alcoholic psychoses were most frequent, and in college men psychoses due to drugs, manic-depressive psychoses and psychopathic personalities were oftener seen. Such studies as Dayton's suggest the psychologic importance of the socioeconomic background.

METHOD OF STUDY

The area sending selectees to the Boston Armed Forces Induction Station is the eastern segment of Massachusetts within thirty-five miles of the seacoast. This area includes wealthy suburban communities, cities with active industries, poor industrial cities of low economic status, towns and villages of less than 2000 population and of varying

economic standards, some isolated rural communities and, finally, city slums in which all the distressing features of extreme poverty are to be found. Probably no more diversified social and economic strata could be found in any one area.

The community unit studied is the area under the jurisdiction of each local selective service board. This unit corresponds to a city ward, part of a small city, a large town or several neighboring small towns. Each community was evaluated and classified in terms of socioeconomic level (desirability). A community's desirability rating was arrived at after consideration of the following fundamental factors: medical care, educational facilities, recreational facilities, public works, "class,"* housing and welfare rates. This index is described elsewhere² in greater detail.

There are six classifications of community desirability; the best rating is A, the poorest F. Most of the communities with A ratings were suburban residential areas near enough to Boston to have the advantages of city life but far enough removed to avoid urban congestion. Most were beyond the 10-cent commuting limit, a significant boundary beyond which the city's poorer elements seldom move. Desirability B includes communities in the wealthier sections of Boston and the best neighborhoods in the other large cities. Desirability C and D represent a wide variety of middle-class communities in cities of all sizes and in some semirural areas. Most of the communities with E ratings were tenement areas in Boston and the other cities. Some of the communities included small slum areas. The F communities, or slum areas, were all in Boston, since it was considered that the worst Boston areas were in a class apart from even the slums of the smaller cities.

*"Class" includes an estimation of the general condition and appearance of houses, stores, factories and business buildings and the distance from the conveniences of a major city, and therefore an area's attractiveness as a residential section.

proach to the problem of occupational diseases as they occurred in the early nineteenth century in America. The essay was published in the *Transactions of the Medical Society of the State of New York*, and since only one hundred copies were printed, did not attract much attention and was not widely read. This reproduction of the text, with the scholarly introduction, is a valuable contribution to the history of the subject, and also to the history of medicine in the United States.

Functional Disorders of the Foot: Their diagnosis and treatment. By Frank D. Dickson, M.D., associate professor of clinical surgery, Medical School, University of Kansas, and orthopedic surgeon, St. Luke's, Kansas City General and Wheatley hospitals, Kansas City, Missouri, and Providence Hospital, Kansas City, Kansas; and Rex L. Diveley, M.D., colonel, M.C., A.U.S., and orthopedic surgeon, St. Luke's, Kansas City General, Research and Wheatley hospitals, Kansas City, Missouri, and Providence Hospital, Kansas City, Kansas. Second edition. 8°, cloth, 352 pp., with 202 illustrations. Philadelphia: J. B. Lippincott Company, 1944. \$5.00.

The second edition of this book, first published in 1939, has been completely revised and rewritten, and much new material has been added to the text. Two new chapters of timely interest have been inserted: one on functional disorders of the foot in relation to military service, and the other on foot disorders in relation to industry. The chapter on constitutional disease affecting the feet has been entirely rewritten.

The American Illustrated Medical Dictionary. By W. A. Newman Dorland, M.D., Lieutenant-Colonel, M.R.C., U.S.A., and member of the Committee on Nomenclature and Classification of Diseases, American Medical Association. With the collaboration of E.C.L. Miller, M.D., Medical College of Virginia. Twentieth edition. 8°, cloth, 1668 pp., with 885 illustrations. Philadelphia and London: W. B. Saunders Company, 1944. \$7.50.

This new edition of an authoritative reference work has been completely revised with additions and alterations on every page. Many hundreds of new words have been included, particularly in the fields of biochemistry, chemotherapy, allergy, endocrinology, vitamin research, tropical and parasitic diseases and mycology. Special attention has been devoted to the vocabulary of war medicine and surgery, as well as to the great number of new synthetic drugs and medical preparations. The terminology of this new edition has been made to conform with the "Standard Nomenclature of Diseases and Operations" of the American Medical Association. This dictionary is remarkable for its system of condensation, resulting in the production of a volume of handy size.

A Manual of Physical Therapy. By Richard Kovács, M.D., professor of physical therapy, New York Polyclinic Medical School and Hospital, attending physical therapist, Manhattan State, Harlem Valley State, Columbus and West Side hospitals, visiting physical therapist, New York City Department of Correction Hospitals, consulting physical therapist, New York Infirmary for Women and Children, and Mary Immaculate Hospital, Jamaica, New York, St. Charles Hospital, Jefferson, Long Island, and Hackensack Hospital, Hackensack, New Jersey. Third edition. 12°, cloth, 309 pp., with 118 illustrations. Philadelphia: Lea and Febiger, 1944. \$3.25.

This small manual, originally entitled *Physical Therapy for Nurses*, was renamed after it had been written, amplified and brought up to date to furnish a comprehensive volume from the viewpoint of wartime and postwar physical therapy. It is intended as an aid in elementary training on the subject, as well as a manual for physicians and medical personnel seeking information on physical therapy. The plan of the manual is to proceed from a brief statement of the basis and the evolution of physical therapy to a systematic presentation of the physics, physical and physiologic effects, clinical uses, technic of application, and dangers and contraindications of each of the principal physical treatment methods. The text is divided into the headings of heat and light, electricity, water, and massage and exercise. The last two chapters have to do with physical therapy in institutional practice and physical therapy in war.

Manual of Human Protozoa: With special reference to their detection and identification. By Richard R. Kudo, D.S., associate professor of zoology, University of Illinois. 11° cloth, 125 pp., with 29 illustrations. Springfield, Ill.: Charles C Thomas, 1944. \$2.00.

This small manual is designed for class use and is based on the author's laboratory notes that have been used in teaching at the University of Illinois. It is intended as a supplement to the large treatises on protozoology. The book contains essential information needed as a practical guide in detecting and identifying the human protozoa. A number of original drawings prepared from living specimens and microscopic preparations have been inserted in the text to supplement the descriptions of the various types of protozoa. This small manual should be of service to all those interested in elementary knowledge of human protozoa.

Freedom from Fear: The interrelation of domestic and international programs. By Louis H. Pink, president of Associated Hospital Service of New York. With a foreword by Owen Young. 8°, cloth, 254 pp. New York and London: Harcourt and Brothers, 1944. \$2.50.

The aim of this small book is to emphasize the importance of domestic measures for social security and to show that these measures are inadequate unless they are supplemented by broad, economic security and universal prosperity. Approximately half the text is devoted to the discussion of various forms of insurance. The book also includes sections on hospitalization, industrial medicine and the cost of medical care, all of which may be of interest to physicians.

NOTICES

SOUTH END MEDICAL CLUB

The eighteenth year of the South End Medical Club will begin on Tuesday, October 17, at 12 noon, at the headquarters of the Boston Tuberculosis Association, 554 Columbus Avenue, Boston.

Dr. Henry Baker, clinical professor of medicine, Tufts College Medical School, will speak on the subject "Stern Puncture Therapy."

Physicians are cordially invited to attend.

ANNOUNCEMENT

Dr. C. A. Cheever announces a change of address: from 464 Beacon Street, Boston, to the Alexander Home, 29 Fir Parish Road, Scituate, Massachusetts.

INTERNSHIPS AND RESIDENCIES AT ST. ELIZABETHS

The Civil Service Commission announces a new examination for rotating internships and psychiatric residencies at St. Elizabeths Hospital, the federal institution for the treatment of mental disorders, in Washington, D. C. The positions pay \$2433 a year, including overtime pay.

The internships consist of nine months of rotating service including medicine, surgery, pediatrics (affiliation), obstetrics (affiliation) and, as conditions permit, psychiatry and laboratory. Applicants must be third-year or fourth-year students in an approved medical school.

The psychiatric residencies consist of nine months in psychiatry. Applicants must have successfully completed the fourth year of study in a medical school and they must have the degree of B.M. or M.D. In addition they must have completed an accredited rotating internship of at least nine months or be serving such internship at the time of making application. Persons who attain eligibility but who are still serving their internship may have their names submitted for appointment but they cannot enter on duty until they have completed their internship.

There are no age limits for this examination and no written test will be given. Applications will be accepted until the needs of the service have been met. Application forms may be secured at first- and second-class post offices, from the commission's regional offices, or direct from the United States Civil Service Commission, Washington 25, D. C.

(Notices continued on page xxi)

signed to measure the subject's ability to learn. though these tests are devised so as to minimize language handicaps, these and cultural handicaps probably affect the test results.

Table 2 shows a steplike increase in the rates of mental deficiency with a decline of socioeconomic level in the community, from 0.9 per cent in the best communities to 3.0 per cent in the poorest. The correlation is further supported by the fact that the average desirability rating for the 11 communities with the highest rates for mental deficiency was above E. In addition, 4 of the 11 were F desirability, in contrast to the fact that 6 of

TABLE 2. *Relation of Percentage Rejected for Mental Deficiency to Community Socioeconomic Level.*

A	0.9
B	1.0
C	1.4
D	1.5
E	2.3
F	3.0

of the 11 with the lowest rates were of A or B desirability.

The finding of high rates of mental deficiency in the lowest socioeconomic group is consistent with the finding of Dayton¹ that psychosis with mental deficiency is the most frequent disorder in the economically dependent group.

The high incidence of mental deficiency in the lower socioeconomic levels can be only partially explained on the basis either of the increased proportions of immigrant families with their language and cultural handicaps or of the biologic differences that have been attributed to them. The explanation does not appear to be complete. It is expected that those who are handicapped by defective intelligence and who fail in the economic competition of society will gravitate into the more undesirable areas, whereas those having the most ability will progress to desirable communities. Furthermore, with inheritance of mental deficiency there tends to be an additional increase of mental deficiency in the poorer communities into which the most defective gravitate or from which they fail to rise.

The explanation of Faris and Dunham³ appears to be extremely pertinent. They say:

Normal mentality and behavior develops over a long period of successful interaction between the person and these organized agencies of society. Defects in mentality and behavior may result from serious gaps in any part of the process. The failure of society to transmit language, for example, or even partial failure through parental neglect of children results in mental retardation of the children.

Psychopathic Personality

Psychopathic personalities, as described in *Mobilization Regulations*,⁶ are an ill-defined group of persons who "manifest a definite defect in their ability to profit by experience . . . [and] are unable to

respond in an adult social manner to the demands of honesty, truthfulness, decency and consideration of their fellow associates." In this group are those who do not conform in their conduct to the dictates of society as a whole or who, by reason of repeated acquisitive, sexual, pugnacious or statutory offenses, together with poor work records and irresponsibility, are considered to be too great trouble-makers to be of use in the Service.

The greatest variation in rejections for psychopathic personality as shown in Table 3 are at the extremes of socioeconomic level. Throughout the intermediate socioeconomic levels, B, C, D and E, there is little variation in the rate for psychopathic personality.

It is notable that of the 15 communities with the extremely high rates, 7 were of the lowest desirability (F) and of population density of over 20,000. Of the 15 communities with extremely low rates, 7 were of A or B desirability and no Boston communities or those of population density over 10,000 are represented.

The explanation of the relation of psychopathic personality to socioeconomic level is not clear, for it is difficult to separate cause and effect. On the one hand, it is known that the psychopath tends to gravitate into the undesirable community; on the other hand, it appears that the stresses and needs

TABLE 3. *Relation of Percentage Rejected for Psychopathic Personality to Community Socioeconomic Level.*

F	6.9

that arise at the low economic levels tend to provoke reactions that are predominantly psychopathic rather than neurotic.

The direct effect of poverty appears to be important. As Burton⁷ stated, "We will turn parasites and slaves, prostitute ourselves, swear and lie, damn our bodies and souls, forsake God, abjure religion, steal, rob, murder rather than endure this insufferable yoke of poverty, which doth so tyrannize, crucify and generally depress us." The natural reaction to the physical stress of poverty appears to be one of anger and acquisitiveness. One reason for the great increase in the rate for psychopathic personality in the F communities over that in the E communities may be that it is only in the former that the real oppression of poverty exists to any marked degree.

It is to be noted that the poorest communities are also the most crowded, and that they contain the highest proportion of foreign-born population or native-born of foreign parents. It is impossible to determine the relative importance of specific immi-

The 60,000 men investigated in the course of this study were examined during the winter, spring and summer months of 1941-1942. The age limits of the first 6000 men were twenty-one to thirty-four, and those of the remainder twenty-one to forty-four years, both inclusive. They were all examined by the same team of psychiatric examiners, using the same criteria for diagnosis. Most of the selectees were unmarried, and no fathers with children born before Pearl Harbor were included.

In determining the relation of mental disorders to socioeconomic level, the percentage of selectees rejected for each disorder from each community was determined, and from this the average rate for communities of like socioeconomic level was calculated. This was done for mental deficiency, psychopathic personality, chronic alcoholism, psychoneurosis, psychoses and the total of these five disorders. Miscellaneous disorders that fell into none of these categories were not studied.

It is recognized that no hasty generalization can be made from the single correlation of mental disorders with desirability. False conclusions may be reached if such major factors as the percentage of foreign-born and natives of foreign-born parents and the density of population are not isolated and their significance considered. It would be an error to attempt to explain our findings without the consideration of both biologic and cultural factors. The emphasis of this paper, however, is only on the cultural factors that exist in the communities studied and are more easily recognized than are the biologic factors. There is no intention of slighting the significance of the latter.

As a working hypothesis it is assumed that the biologic factors of importance in mental disorders interact with environmental factors, the influence of which is such that the prevalence of mental disorders within a community varies with the amount of mental stress and with the availability of the normal emotional outlets of recreation, religion, home life and work. The types of mental disorders vary both with the type of mental stress and with the cultural acceptability of different emotional outlets.

RESULTS

The relation of desirability to the total of the major causes of psychiatric rejection is presented in Table 1. It shows a steplike increase in the proportion of selectees disqualified for the major rejection causes from the best to the worst communities.

A comparison between the communities with extremely high rejection rates and those with extremely low rates yields the following results: In 13 communities with the highest rejection rates, the average desirability rating was E, there were 7 F communities (only 9 communities in the entire area were given F ratings), and 8 communities were in Boston. In thirteen communities with the lowest rates, the average desirability rating was B, not a

single community was in Boston, 9 communities were suburbs of Boston, and no community was in the lower half of the desirability scale (D, E or F).

The finding of an increased rate of psychiatric disorders in the poorest communities suggests that the low socioeconomic level may be of etiologic im-

TABLE 1. *Relation of Total Major Psychiatric Causes of Rejection to Community Socioeconomic Level.*

D	15,000	10.0
E	8,650	12.7
F	6,750	16.6

portance. The finding is in agreement with that of Faris and Dunham,³ who found that the highest admission rates for mental disorders occurred in the poorest areas of the city (Chicago). This condition may be the result of several factors. The importance of socioeconomic level is further demonstrated in the consideration of communities of the same population density. It was notable that 12 of the 14 communities that had unusually low rates for mental disorders were of a higher socioeconomic level than the average for the density level in which they were classified.

Certain factors that must be considered to affect the relation of mental disorders to socioeconomic level are those of difference in population density, in proportions of people of foreign birth, and in nationality, which are associated more closely with certain socioeconomic levels than with others. The fact that people with special physical and mental handicaps gravitate into the communities of the lowest socioeconomic level and also fail to rise from such communities to better ones is of acknowledged importance. In general, however, a great part of the findings must be attributed to the true influence of the different socioeconomic levels rather than to the influences of these interrelated factors. The respective influence of population density and of nationality will be considered in subsequent papers.^{4, 5}

Since each mental disorder appears to bear a different relation to socioeconomic level, as has been suggested by the work of Dayton¹ and that of Faris and Dunham,³ the major psychiatric rejection causes are considered separately.

Mental Deficiency

To state exactly the minimum intelligence standards except in terms of the score on the tests used would be difficult, but it may be said that in general the test procedure was designed to disqualify men whose mental age was estimated to be below ten years.

Mental ability is determined by a team of psychologists, using a series of psychometric tests

ie explanation for this, according to Gillespie,⁹ is pressed in the maxim, "He that is down need fear fall."

The distribution of different nationalities at different socioeconomic levels may be important, for the studies of mental disorders and nationalities great variation in rate of psychoneurosis was found. Whereas mental deficiency, psychopathic personality and chronic alcoholism are all associated with economic and social failure, thus preventing the subject from climbing the socioeconomic ladder, the reverse is true in the majority of the cases of psychoneurosis. The neurosis may be part of their drive or ambition. It may be either the cause or the result of ascent of the social or economic ladder. The subject can be severely neurotic and still be extremely successful. Hence, if there is any inheritance of a neurotic disposition, persons with this inheritance would be likelier to reach higher socioeconomic levels than would be those inheriting biologic limitations of intelligence.

Beard¹⁰ was perhaps correct when he postulated that America is a nation of neurasthenics, and that the condition is fostered by American ambition and is therefore most prevalent in the great American middle classes. Other explanations are found, first in the difference in the types of stress to which those at the various socioeconomic levels are subjected; and secondly, in the differences in acceptability of emotional outlets in communities of varying culture.

When the needs of persons in the desirable communities, which are usually intellectual, are frustrated and stress ensues, they are less apt to behave in the asocial manner of the psychopath than are those in the slums when their needs, which are usually more elementary or physical, are frustrated. Furthermore, the asocial behavior of the psychopath is not acceptable at the upper social levels, since the members of the most desirable communities are more restrained by the laws and customs of society. The boy in the gang in the slums reacts to stress by surpassing the gang in whatever exploits of drinking, fighting, car-stealing or girl-chasing it is engaged in; the boy in the better community reacts to his less elementary type of frustration by means of nervous indigestion, headaches and anxiety. Hence, chronic alcoholism and psychopathy are found in the poorer communities and psychoneurosis in the more desirable ones.

Biologic explanations cannot be ignored. Presumably some people are constitutionally predisposed either to psychopathy or to neurosis. The true picture is probably one of the interplay of different cultures on different predispositions. What is important at this point is the clear distinction between psychoneurosis and psychopathy in their occurrence in the communities of various socioeconomic levels.

Psychoses

Because those hospitalized for mental disorders, as well as many with histories of such hospitalization, are not being submitted for examination, data on the psychoses are not representative of the true incidence of psychoses in the population. Consequently, far less importance can be attached to our findings in this particular realm of psychiatric disorders. The data seem worthy of presentation, however, for they do represent psychotic cases in the general population in the area studied.

Table 6 shows a definite increase in incidence of psychoses in the poorer socioeconomic levels over that in the best communities, with the communities of intermediate desirability, B to E, having intermediate rates not significantly different from each

TABLE 6. *Relation of Percentage Rejected for Psychosis to Community Socioeconomic Level.*

F	0.45

other. This pattern most closely resembles that of psychopathic personality and does not resemble that of psychoneuroses. The findings correspond roughly to those of Faris and Dunham³ in their report on institutionalized psychotic patients in Chicago.

The gravitation of the inadequate to the lower socioeconomic level must be considered as an important factor, for the psychoses, like all mental disorders except psychoneurosis, are conditions that are socially and economically handicapping to such an extent that they prevent their victims from rising to a higher socioeconomic level. In so far as inheritance is a factor in producing a predisposition toward mental disorders, it might be expected that the influence of inheritance would be greatest in communities where there are the largest number of persons with mental disorders — in this case, in the communities of lower desirability. It is probable that withdrawal as a result of submission to the stress of life, a symptom seen in dementia praecox, the most frequent psychosis in the selectee age group, is most frequent at the lowest socioeconomic level. In explaining the incidence of psychoses it is probably necessary to consider both biologic and cultural factors. To do so requires study of the true proportion of psychotic persons to be found in society, either institutionalized or otherwise, a project beyond the scope of this study.

grant stresses and cultural differences among people of foreign origin as factors in the increase of psychopathy. It might be pointed out, however, that no one nationality is especially prevalent in the undesirable communities. Mediterranean groups, Irish, Canadians, Negroes and Old Americans are all well represented. It can be inferred that causal factors are not associated with any one race, but are associated with any national group that inhabits the undesirable community, a fact that Shaw⁸ emphasized.

Chronic Alcoholism

According to *Mobilization Regulations*,⁶ the criterion of disqualification for chronic alcoholism is defined as follows: "An individual will be regarded as a chronic alcoholic if he habitually uses alcohol to a point of social or physical disability, as evidenced by loss of job, repeated arrests, or hospital treatment because of alcoholism." As shown by Table 4, there is no significant variation in the per-

TABLE 4. Relation of Percentage Rejected for Chronic Alcoholism to Community Socioeconomic Level.

SOCIOECONOMIC LEVEL	PERCENTAGE REJECTED

B	0.9
C	0.9
D	1.2
E	1.5
F	2.8

centage rejected for chronic alcoholism throughout the most desirable half of the communities, with a variation only from 0.9 to 1.2 per cent in the levels A through D.

The fact that the rates of alcoholism bear no relation to socioeconomic level in the higher brackets suggests that other factors correlate more closely with alcoholism. The greater population density in the communities of D, E and F desirability may account, at least in part, for the increase in chronic alcoholism in those communities. In general, within a given socioeconomic level there is found a tendency for alcoholism to increase in the denser communities.

It may appear significant that the 11 communities with extremely high rates for alcoholism had an average desirability of E, as compared to the average of less than C for the 11 communities with extremely low rates. The 6 F-desirability communities that had extremely high rates, however, were also of the highest population density, over 20,000, suggesting that density may be the primary factor.

On the whole, heavy drinking and drunkenness are less taboo in the poor, low socioeconomic communities than throughout the upper and middle desirability brackets. Heavy drinking as an emotional outlet and as a form of social and physical relaxation is acceptable in the culture of the labor-

ing classes, who make up the lowest desirability brackets. The tavern is the poor man's club, and when he "accidentally" overindulges and become drunk, he has committed no great moral or social transgression; he has suffered no such loss of social prestige as might occur in the higher social strata. With greater cultural acceptability of hard drinking and drunkenness, it is not surprising that alcoholism is increased in the poorer communities. With the use of alcohol as an outlet for emotional stress and for physical relaxation, outlets such as neurosis are less necessary, as is apparent in the next consideration.

Psychoneurosis

A well-defined psychoneurosis of any type is considered disqualifying for military service. Some of the symptoms and types are designated in *Mobilization Regulations*⁶ as conversion symptoms, hysterical paralysis, vasomotor disturbances, excessive concern over minor or imaginary bodily ailments, obsessions, compulsions, phobic manifestations and emotional disturbances.

The relation of psychoneurosis to community socioeconomic level (Table 5) differs from that of the mental disorders previously considered in that there is no significant increase in psychoneurosis with decreased socioeconomic level. There is no appreciable rise when communities of extremely high rates are compared with those that have low rates. Ten communities with the highest rates for psychoneurosis had an average desirability rating of D and those with the lowest rates a rating of C. This is

TABLE 5. Relation of Percentage Rejected for Psychoneurosis to Community Socioeconomic Level.

SOCIOECONOMIC LEVEL	PERCENTAGE REJECTED
A	2.9
B	3.7
C	3.8
D	3.4
E	4.7
F	3.4

the smallest comparative difference observed in any of the mental disorders.

In 8 of the 10 communities with extremely high rates, the desirability rating was either C or D. On the other hand, 6 of the 10 communities with extremely low rates were also in the C or D brackets. These findings suggest that there is little or no relation between psychoneurosis and socioeconomic level.

The relatively low rates of psychoneurosis in the poorer communities confirm the findings of Newstatter.⁹ His study showed that nervousness of nearly all kinds was actually less frequent among children of the poor than among children of the well-to-do. Twenty per cent of the children of the poorer families and 38 per cent of those of the well-to-do parents had nervous or neurotic symptoms.

The explanation for this, according to Gillespie,⁹ is expressed in the maxim, "He that is down need fear no fall."

The distribution of different nationalities at different socioeconomic levels may be important, for in the studies of mental disorders and nationalities a great variation in rate of psychoneurosis was found.

Whereas mental deficiency, psychopathic personality and chronic alcoholism are all associated with economic and social failure, thus preventing the subject from climbing the socioeconomic ladder, the reverse is true in the majority of the cases of psychoneurosis. The neurosis may be part of their drive or ambition. It may be either the cause or the result of ascent of the social or economic ladder. The subject can be severely neurotic and still be extremely successful. Hence, if there is any inheritance of a neurotic disposition, persons with this inheritance would be likelier to reach higher socioeconomic levels than would be those inheriting biologic limitations of intelligence.

Beard¹⁰ was perhaps correct when he postulated that America is a nation of neurasthenics, and that the condition is fostered by American ambition and is therefore most prevalent in the great American middle classes. Other explanations are found, first in the difference in the types of stress to which those at the various socioeconomic levels are subjected; and secondly, in the differences in acceptability of emotional outlets in communities of varying culture.

When the needs of persons in the desirable communities, which are usually intellectual, are frustrated and stress ensues, they are less apt to behave in the asocial manner of the psychopath than are those in the slums when their needs, which are usually more elementary or physical, are frustrated. Furthermore, the asocial behavior of the psychopath is not acceptable at the upper social levels, since the members of the most desirable communities are more restrained by the laws and customs of society. The boy in the gang in the slums reacts to stress by surpassing the gang in whatever exploits of drinking, fighting, car-stealing or girl-chasing it is engaged in; the boy in the better community reacts to his less elementary type of frustration by means of nervous indigestion, headaches and anxiety. Hence, chronic alcoholism and psychopathy are found in the poorer communities and psychoneurosis in the more desirable ones.

Biologic explanations cannot be ignored. Presumably some people are constitutionally predisposed either to psychopathy or to neurosis. The true picture is probably one of the interplay of different cultures on different predispositions. What is important at this point is the clear distinction between psychoneurosis and psychopathy in their occurrence in the communities of various socioeconomic levels.

Psychoses

Because those hospitalized for mental disorders, as well as many with histories of such hospitalization, are not being submitted for examination, data on the psychoses are not representative of the true incidence of psychoses in the population. Consequently, far less importance can be attached to our findings in this particular realm of psychiatric disorders. The data seem worthy of presentation, however, for they do represent psychotic cases in the general population in the area studied.

Table 6 shows a definite increase in incidence of psychoses in the poorer socioeconomic levels over that in the best communities, with the communities of intermediate desirability, B to E, having intermediate rates not significantly different from each

other. This pattern most closely resembles that of psychopathic personality and does not resemble that of psychoneuroses. The findings correspond roughly to those of Faris and Dunham³ in their report on institutionalized psychotic patients in Chicago.

The gravitation of the inadequate to the lower socioeconomic level must be considered as an important factor, for the psychoses, like all mental disorders except psychoneurosis, are conditions that are socially and economically handicapping to such an extent that they prevent their victims from rising to a higher socioeconomic level. In so far as inheritance is a factor in producing a predisposition toward mental disorders, it might be expected that the influence of inheritance would be greatest in communities where there are the largest number of persons with mental disorders—in this case, in the communities of lower desirability. It is probable that withdrawal as a result of submission to the stress of life, a symptom seen in dementia praecox, the most frequent psychosis in the selectee age group, is most frequent at the lowest socioeconomic level. In explaining the incidence of psychoses it is probably necessary to consider both biologic and cultural factors. To do so requires study of the true proportion of psychotic persons to be found in society, either institutionalized or otherwise, a project beyond the scope of this study.

COMMENT

Relations have been established between community socioeconomic level and the total rate of major mental disorders and between each of the major mental disorders. That the relations thus established are not the same for all disorders is in agreement with the findings of Faris and Dunham³ in their study of hospital admissions from different areas of Chicago. It is significant that a study of disorders severe enough to require hospitalization and a study of disorders among supposedly normal selectees examined for induction into the armed forces should reach similar conclusions. The findings of this study suggest that those of Faris and Dunham represent the true conditions and cannot be attributed to the selective factor involved in hospitalization.

Various explanations of the causes of the relation of mental disorders to community socioeconomic level have been offered, not because these explanations are considered final and capable of proof, but to stimulate further research. Intensive study of the interrelation of biologic and environmental factors in mental disorders is essential.

Further differentiation of disease entities and variation in symptomatology due to the cultural differences is necessary to explain such findings as higher rates for psychoneurosis in the best communities and for psychopathic personality in the poorest.

The influence of the mobility of the unfit in their gravitation into the undesirable areas must be evaluated. The influence of both biologic differences in the foreign-born and their children and their specific cultural differences and handicaps must be isolated. The interrelation of socioeconomic level, nationalities and occupation with population density must be found.

An attempt will be made in two subsequent papers^{4, 5} to present the relation of mental disorders to population density and to race and nationality, but these papers likewise point out the immensity of the field yet to be investigated.

SUMMARY

The rejection rates for the major causes of mental rejections in 60,000 selectees examined at the Boston Armed Forces Induction Station were determined and classified according to the socioeconomic level of the community from which the selectees came. An attempt was made to show the relation of mental disorders to socioeconomic factors.

The total incidence of major mental disorders increased gradually from 7.3 per cent in the best communities to 16.6 per cent in the poorest communities.

There was a steplike increase in the rate of mental deficiency as socioeconomic level of the community declined, from 0.9 per cent in the best communities to 3.0 per cent in the poorest.

The rate of psychopathic personality increased from 2.4 per cent in the best communities to 6.9 per cent in the poorest. In spite of the wide difference at the extremes there was little variation among communities of intermediate desirability levels.

The rate for chronic alcoholism did not vary significantly in the better half of the communities (A, B and C desirability) and increased only in the poorest and densest (D, E and F) communities, suggesting that socioeconomic level per se is secondary in importance to density of population in determining the incidence of chronic alcoholism.

The rate for psychoneurosis showed no consistent variation with socioeconomic level. There was no increase in the poorer communities, whereas throughout the communities of intermediate desirability there was a slight increase.

The rate of psychoses increased with declining socioeconomic level, and variation from the average was most marked at the two extremes of desirability.

These findings were explained on the basis of gravitation of the more unfit into the poorer communities and of differences in cultural acceptability of asocial conduct at different socioeconomic levels. Exceptions due to population density and nationality were considered and will be presented in full in subsequent papers.

UTERINE BLEEDING AND THE ROENTGENOLOGIST*

JOE VINCENT MEIGS, M.D.†

BOSTON

ABNORMAL uterine bleeding is perhaps the most frequent abnormality of the menstrual cycle. The causes of such bleeding are many, and before proper treatment can be instituted consideration should be given to the various physiologic changes that may be responsible. It is not sufficient to do a dilatation and curettage, give the patient radium or x-ray treatment or remove the uterus, for correction may be by way of some endocrine preparation or vitamin or even something as remote from pelvic attack as splenectomy. One of the greatest mistakes that can be made is to treat bleeding patients without proper investigation; surely, before x-rays are directed toward the ovaries the reason for the bleeding must be as clear as possible. Patients with scurvy or purpura should not be given x-ray treatment, and its use to check bleeding that may be due to cancer of the fallopian tube or endometrium is to be condemned. In the presentation of this subject a review of the various changes that may be responsible for abnormal bleeding is considered first, with a discussion of the means at one's disposal to correct such abnormalities. Lastly, the various methods of surgical and radiologic attack are discussed.

TYPES OF ABNORMAL BLEEDING

Physiologic Disturbances

The first consideration should be given to a description of the constitution of menstrual blood. Is it different from normal blood? Does it contain an anticoagulant or a toxic product, or can normal physiology explain its characteristics? In 1942 Lozner, Taylor, and Taylor¹ presented a well-thought-out and well-controlled series of experiments that showed that menstrual blood and defibrinated blood or serum react similarly to the addition of thrombin, prothrombin and fibrinogen. Their experiments demonstrated that menstrual blood is blood that has already clotted within the uterine cavity. They explain the lack of clots as seen in the menstrual flow as due to the fact that menstrual blood is slowly excreted, and they believe that there may be some lytic substance within the uterine cavity. In most patients small clots are usually found, and having taken histories for many years from patients on this point, I can agree. The experimenters showed that when prothrombin or fibrinogen was added to menstrual blood, clotting occurred. They indicate that menstrual blood has sufficient clot-promoting activity

to clot if prothrombin and fibrinogen are added to it. This reaction to prothrombin and fibrinogen is similar to that of defibrinated blood or serum. Their work demonstrates that menstrual blood as passed from the vagina consists of serum, clots and debris, and that clotting should take place before the menstrual fluid reaches the vagina. It is obvious, therefore, that any interference with the normal structure of the uterus or of the normal constituents of the blood may be a cause of abnormal bleeding.

Another primary consideration is an understanding of the coagulation of blood. It is usually accepted that blood clots because calcium, prothrombin and blood platelets act together to form thrombin, an active coagulant. Thrombin with fibrinogen forms fibrin, the basis of the blood clot so that interference with any of the above constituents of blood may prevent clotting and hence cause abnormal menstrual flow. Lozner, Taylor and Taylor have explained that coagulation nearly always takes place within the uterus. If, for instance, the blood platelets are few or absent, thrombocytopenic purpura results. A deficiency of calcium may be a cause of abnormal bleeding. Certainly a deficiency of prothrombin is a cause, and such abnormal bleeding may easily occur during the phase of uterine bleeding. There are possibilities for bleeding in any changes that occur in the physiologic characteristics of blood.

Certain of the blood dyscrasias, such as thrombocytopenic purpura, are definitely associated with abnormal uterine bleeding, and nearly every year a case of bleeding requiring splenectomy, not hysterectomy, is seen in the wards of the hospital. Certainly some of the leukemias evidence uterine bleeding as a symptom. There are other abnormalities of the cellular blood elements that may be responsible for bleeding.

Before consideration can be given to hormones as being responsible for abnormal bleeding, or before sympathetic-nerve control of uterine blood vessels can be discussed, the present conception of menstruation must be explained. Normal menstruation recurs cyclically — why, no one knows. It occurs normally only during certain years in the lives of women. Before and after these normal years any uterine flow must be considered as abnormal until proved otherwise. Normal menstruation occurs after a follicle, secreting estrin, has grown and ruptured and a corpus luteum, secreting progesterin, has grown and retrogressed. It occurs when both estrin and progesterin are low in amount. Markee² has pointed out that before the time of menstruation the edema of the premenstrual phase lessens and the endometrium becomes thinner. At

†Chief of the Vincent Memorial Hospital at the Massachusetts General Hospital; clinical professor of gynecology, Harvard Medical School.

the same time the veins of the endometrium are swollen and congested and the return flow of blood from the endometrium is delayed. This is due to a constriction of the smooth muscle of the uterus. Some of the veins rupture, some leak blood by rhexis, and hematomas are found lifting up the endometrium. Later, owing perhaps to a direct hormonal influence or to sympathetic control, the spiral arteries become shut off. Anoxemia then occurs, sloughing commences, and the endometrium is cast off. The open spiral arterioles present into the uterine cavity. Later these arteries relax, a few at a time, and bleeding takes place from them into the uterine cavity. This is a rhythmic process, and because only a few spiral arteries bleed at a time, severe hemorrhage does not take place. The basal layer of the endometrium with its straight arteries is not injured, and because of this, repair takes place and the endometrium covers the raw surface and bleeding ceases. Ovarian hormones are responsible for some of this effect, but whether the effect is on the muscles of the uterus or the walls of the veins and arteries or their nerve apparatus is unknown. It is reasonable to assume that some of the activities of the blood vessels are due to the influence of the sympathetic nervous system and its mediator, sympathin (adrenaline). There is definite evidence of a hormonal control, for without hormones, as in the menopause, normal uterine bleeding does not occur.

There has long been a theory that the initiation of menstrual bleeding is due to the lowering of the titer of estrin. In the castrated patient, cessation of estrin treatment is often followed by bleeding. If, however, estrin and progestin are given together, withdrawal of estrin is not followed by bleeding but withdrawal of progestin is. Thus, bleeding can be precipitated by the withdrawal of either hormone.

A definite type of bleeding is seen in those patients who do not ovulate. In this group, bleeding may be fairly regular and yet a normal cycle is not present, for progestin is absent. Ovulation does not occur in the cases of abnormal bleeding oftenest seen, that is, those of metropathia hemorrhagica.

Control by the sympathetic nervous system must be a factor in some cases, for section of the spinal cord often precipitates bleeding. It is well known that within three days after presacral neurectomy, no matter what the time of the cycle, bleeding nearly always occurs. Anger and fright are well known as precipitators of menstrual cycles. It is quite possible that hormones and nerve control go hand in hand and that one affects the other. It is certain, however, that the former are the more essential of the two, for without them physiological bleeding does not occur.

Hormonal Dysfunction

The most frequent hormonal pattern of abnormal bleeding is that so often seen in early and late menstrual life. This type of bleeding has been called metropathia hemorrhagica; it is characterized by hyperplasia of the endometrium, a sizable follicle cyst of the ovary, wrinkling of the rest of the ovarian tissue and the absence of corpus luteum. The history is usually fairly typical — an occurrence of normal or large periods followed by continuous flowing or, as is most usual, a period of amenorrhea followed by prolonged flowing. Young patients are not usually operated on, but in certain ones that have been such an ovarian picture has been encountered. In patients in the menopause group when the ovaries are ceasing to function it is not at all uncommon. The treatment should be simple — the institution of a corpus luteum-stimulating hormone or substitution of corpus luteum itself. Since there is no satisfactory corpus luteum-stimulating hormone, progestin or the corpus-luteum hormone is frequently used and with good effect. This hormone is given on successive days, and after its withdrawal a normal period occurs from a secretory endometrium. After three successive cycles the treatment is stopped, and in about 50 per cent of cases a normal cyclic rhythm is established. This group of patients may also be treated by large doses of estrin or of testosterone with about the same results.

Other cases of bleeding, such as those resulting from a secretory endometrium, are not so clearly understood, and it is possible that they fall into another group. In certain cases, young patients have large, white ovaries through which ovulation cannot take place. They usually have amenorrhea but may complain of continuous bleeding. This bleeding is due to the persistent secretion of small amounts of estrin. Transecting or peeling the ovary in such a way as to allow ovulation to take place usually relieves the situation. The hormone that is the ordinary cause of bleeding is estrin; it is usually present in small but persistent amounts and is not interrupted by ovulation. Bleeding due to hyperplasia of the endometrium is the same sort of phenomenon.

Included under hormonal causes of bleeding from the uterus are the various tumors of the ovary that secrete estrin and therefore cause the estrin type of bleeding or the type that is found in the anovulatory cycle. Granulosa-cell tumors, thecomas and certainly many ovarian cysts that secrete estrin cause such bleeding. This bleeding comes from an estrin-phase endometrium. It is obvious, then, that the real cause of hormonal bleeding is the uninterrupted production of estrin, usually of a small but persistent amount.

Vitamin Deficiencies

Next to be considered is the bleeding due to vitamin deficiencies. The most obvious type is that due to vitamin C deficiency, or scurvy. In scurvy, continuous bleeding may be slight, severe or prolonged. The cure is to replenish the body with vitamin C. Prothrombin deficiency due to liver injury may be a cause of abnormal bleeding, and a prothrombin deficiency due to lack of vitamin K, either because of lack of it or because of injury to the bile-salt supply, does the same thing. Biskind and Biskind³ have recently found that perfect conjugation of estrogen in the liver may be impossible without sufficient vitamin B, and it is possible that such a deficiency is responsible for abnormal bleeding from the uterus.

Nerve Factors

The central nervous system probably plays no part in the control of the bleeding, but the sympathetic system, with its action on the blood vessels through its mediator sympathin (adrenaline), must and does affect bleeding. As described above, injury to the spine or injury by surgery to the superior hypogastric plexus brings about sudden bleeding.

Pathologic Lesions

Certain lesions may in themselves be the cause of bleeding because of changes in the shape of the uterine cavity, because of interference with the normal blood-vessel control or because bleeding may occur directly from a broken blood vessel, as in a tumor.

A *polyp of the cervix* bleeds because of trauma to its surface or lack of blood supply to its tip and subsequent necrosis. A *polyp of the endometrium* bleeds because of interference with its blood supply or that of the endometrium, which it abuts, or because of interference with the normal contraction of the uterus and closure of its cavity. *Leiomyomas* or *fibroids* are responsible for bleeding because of interference with the normal contracting mechanism of the uterine wall or with the blood vessels of the endometrium, or because, as in submucous fibroids, they present a greatly increased bleeding surface. It is possible that because of their position they interfere with the endometrial blood supply, whether they are submucous or intramural. Any lesion that increases the surface of the endometrial cavity causes abnormal bleeding, for the amount of blood lost from an increased surface cannot clot and disintegrate within the uterus — hence the occurrence of bright bleeding and clots. In a large number of cases, however, fibroids bleed because there is an accompanying endocrine disturbance. This dis-

turbance is always that of anovulation, and anovulation is responsible for the type of bleeding seen in metropathia hemorrhagica. Patients with *pelvic inflammation* bleed because the ovaries, buried in adhesions, cannot ovulate and a follicle cyst is formed that secretes estrin. No ovulation occurs, and metropathia hemorrhagica therefore exists. *Ovarian cysts* cause bleeding because they often secrete low but persistent amounts of estrin and produce an estrin-phase endometrium that eventually bleeds. *Cancer of the cervix* bleeds because pieces of cancer become necrotic and break off, and because the tumor itself is sometimes traumatized. *Cancer of the endometrium* bleeds because pieces of tumor become necrotic and because constriction of the uterus injures the delicate tumor mass. Patients with *cancer of the fallopian tube* bleed because pieces of tumor often slough and the subsequent bleeding seeps through the tube and into the uterus.

TREATMENT

The practitioner must decide what the proper treatment of each case of bleeding is. He must first try to decide why the bleeding occurs and whether or not the problem is a medical one, as contrasted to surgery and radiation. If the bleeding is due to a blood disease, a lack of a normal component of blood coagulation, a vitamin deficiency or a hormonal disturbance, treatment can be undertaken along proper lines, but if such a diagnosis cannot be made, the patient should be treated as though the bleeding were due to malignant disease and a biopsy and curettage should be done. For medical treatment there are available estrin, progestin, testosterone, vitamin C, vitamin K, vitamin B and transfusion.

If the cause of the bleeding is not obvious, the patient must *not* be sent directly to the roentgenologist for x-ray treatment. This is a most important point. No roentgenologist, except under very exceptional circumstances, should attempt treatment with x-rays unless a diagnostic curettage and biopsy has been done. This is because x-ray treatment may stop the bleeding from a cancer and mask a serious situation. Roentgen therapy rarely cures cancer. Cases can be found where x-ray treatment has cured uterine cancer, but they are very few. The treatment of cervical cancer with x-ray alone, unless deliberately done and supplemented by vaginal-cone treatment, is wrong. X-ray treatment can prevent bleeding until the tumor has advanced to a much less treatable stage. If the cause of bleeding is in doubt, — and it usually is, — a biopsy of the cervix and endometrium should be done. Then, and then only, can x-ray treatment be correctly given for so-called "benign bleeding."

It is my opinion that ovarian function is worth preserving. Castration is followed by the menopause and its accompanying changes, such as vaginal atrophy, lack of interest in sex and alterations in the skin and bones. X-ray and radium treatment should be avoided when it is possible to remove the uterus and cervix and leave the ovaries in place. At the Pondville Hospital an ovary recently was seen with a fresh corpus luteum in it seventeen years after hysterectomy. It is easy for a surgeon to be biased, but having seen and cared for a great many patients that have had x-ray and radium therapy for benign bleeding, I am convinced that it is better, whenever possible, to save ovarian function.

A patient past the menopause should never be treated by radium and x-ray to stop bleeding. If a curettage does not reveal the cause of the bleeding, nothing more should be done. If the bleeding recurs it is best to curette again, and if it again recurs it is best to remove the uterus. X-ray treatment in moderate doses may prevent bleeding from cancer, and the treatment of cancer should be carried out as early as possible. Mistakes of this type have been observed in various clinics, and some patients are in a hopeless condition when seen, although they have had freedom from symptoms for definite periods of time. Cancer is curable in its early stages, but early recognition and adequate treatment are essential.

X-ray and radium should be reserved for the treatment of bleeding in spinsters near the menopause or for patients in such poor physical condition that they cannot stand a major surgical procedure. Surgery in a strong, healthy woman is safe, and the removal of the cervix is a boon to woman-

kind. Total hysterectomy with conservation of the ovaries is one of the most satisfactory of all surgical procedures.

SUMMARY

There are many reasons for uterine bleeding of the abnormal type. Care must be taken to rule in or out all the possibilities.

Some of the causes of bleeding are deficiency of normal blood-clotting components, hormonal dysfunction, vitamin deficiencies, injury to the sympathetic nervous system and blood diseases.

Benign and malignant tumors constitute the largest group of patients with abnormal bleeding.

No patient should be subjected to x-ray or radium treatment without proper histologic study of tissue from the cervix and endometrium.

Removal of the uterus and cervix, with conservation of the ovaries, is the proper treatment for patients with fibroids and benign tumors.

Cancers should be given their proper treatment, whether it is surgery, radium, x-ray or all these, undertreatment being worse than none.

Patients bleeding past the menopause should never be given x-ray or radium treatment until the bleeding has been adequately explained.

ADVANCES IN INHALATION THERAPY, WITH PARTICULAR REFERENCE TO CARDIORESPIRATORY DISEASE*

MAURICE S. SEGAL, M.D.†

BOSTON

THE present report centers particularly about the use of oxygen, helium-oxygen mixtures, inhalation sprays of bronchodilator, vasoconstrictor, aminophyllin and sulfonamide solutions and positive pressure therapy in a series of 49 cases of pulmonary or cardiac disease demonstrating anoxia, obstructive breathing or pulmonary edema, alone or in combination.

The effectiveness of inhalation therapy depends to a large extent on the type of equipment used. In the present study, the new B. E. M. (Barach-Eckman-Molomut¹⁻³) mask and the helium-oxygen hood apparatus^{4, 5} were used for the routine administration of oxygen or helium-oxygen mixtures. The mask can be used to deliver 40 to 95 per cent oxygen or helium-oxygen mixtures and is metered for positive pressure in the expiratory phase of respiration. The ventilated hood is the most effective apparatus for giving oxygen or helium-oxygen mixtures with increased pressures. Positive pressures up to 6 cm. of water can be applied to the inner surface of the lung during both inspiration and expiration. A detailed description and comparisons with other equipment have previously been published.⁶ For the administration of nebulized substances by the pulmonary route, the Vaponefrin nebulizer has proved most efficient. It produces a very fine, voluminous spray or smoke screen. The technic and value of employing continuous vaporization therapy may be found in papers by Barach and his associates,⁷⁻⁹ Lockey,¹⁰ Castex et al.,^{11, 12} Chambers et al.,¹³ Harris et al.,¹⁴ Norris,¹⁵ Stacey,¹⁶ Krueger et al.¹⁷ and the author.^{6, 18, 19, 29}

CLINICAL STUDY

Material

In this study 21 patients were treated for bronchial asthma, 6 for atypical pneumonia, 4 for bronchopneumonia in combination with organic heart disease and failure, 4 for pulmonary edema and anoxia associated with renal decompensation, 4 for pulmonary edema associated with acute left-ventricular failure, 3 for inhalational gas poisoning, 3 for chronic bronchiectasis, severe pulmonary emphysema and fibrosis, 1 for massive atelectasis of the entire right lung, 1 for atelectasis of the right lower lobe in association with severe rheumatic heart disease, cardiac failure and pregnancy, 1 for

respiratory obstruction following postoperative thyroidectomy, and 1 for rapid respiratory decompensation following splenectomy.

Fatal Cases

There were 12 deaths in this series. Autopsies proved that 8 cases were hopeless from the outset. This leaves a corrected mortality of 4 out of 41 cases, and it is questionable whether these could have been saved by any type of therapy. Two of these patients were moribund from the outset and survived only two days. Striking clinical improvement with relief of anoxia and obstructive manifestations were repeatedly observed, even though temporarily, in most of the fatal cases. A few typical case histories follow.

CASE 1. A 28-year-old woman with a diffuse, bilateral, virulent type of atypical pneumonia associated with lesions of the mucosa of the mouth and upper airways was moribund for a day before therapy was started. She regained consciousness and survived for 7 days in almost continuous residence in the hood apparatus. She died suddenly while being transferred from the hood to a tent apparatus.

CASE 2. A 48-year-old man with a diffuse bronchopneumonia following a subtotal gastrectomy demonstrated marked anoxia and pulmonary edema before he was placed in the hood apparatus. Conventional mask and tent oxygen therapy had been previously attempted without success. Within a period of 4 days, he responded successfully to a complete program of physiologically directed therapy and was comfortable and well without any further therapy. At that point, the abdominal stay sutures were removed and evisceration followed. The course thereafter was rapidly downhill and the patient died 3 days later. The autopsy revealed no ill effects from the sustained positive-pressure therapy.

CASE 3. A 43-year-old woman had a history of severe rheumatic heart disease of many years' standing. The terminal picture was characterized by repeated attacks of pulmonary edema, associated with a diffuse pneumonia. She was moribund at the outset and catheter, mask and tent oxygen had been of no avail. In the hood apparatus, she was given 100 per cent oxygen concentrations under positive pressures up to 5 cm. of water. The pulmonary edema was easily controlled in this way. She regained consciousness and for 2 days the prognosis was brighter. Death came suddenly on the 5th day of inhalation therapy. The autopsy revealed an almost completely stenosed mitral valve with a large vegetation filling the left auricle. The lungs showed little evidence of pulmonary edema, and there was no evidence of ill effects from the sustained positive pressures.

The pulmonary findings in the last case were the same as those found in the other two reported cases receiving positive pressures over periods of at least 4 days in the hood apparatus.

Living Cases

In the patients who survived, it was the opinion of many observers that death from respiratory decompensation was imminent in many of the cases. In the patients with atypical pneumonia, the hack-

he degree of bronchospasm. I found that 1 per cent Neo-Synephrin was an effective vasoconstrictor of the tracheobronchial tree; it was particularly effective in controlling excessive secretions, as observed in cases of inhalational gas poisoning and some cases of atypical pneumonia and bronchial asthma. It can be effectively directed into the tracheotomy opening when necessary. It is a poor bronchodilator. Refractoriness to it usually does not develop. A slowing of the pulse rate may be observed. Occasionally, restoration of adrenalin sensitivity follows its use. Epinephrine is an effective bronchodilator. The Vaponefrin preparation was generally found to be the most effective. The combination of Neo-Synephrin and Vaponefrin was particularly effective in severe bronchospasm associated with profuse expectoration.

Continuous vaporization sprays of aminophyllin solutions were tried in a number of patients with bronchial asthma. Effective therapy may frequently be obtained with 0.5 to 0.7 gm. The volume of solution necessary and the expense involved militate against its general usage in this way, particularly when it is so effective rectally.

In a few patients with chronic bronchiectasis and pulmonary fibrosis, continuous vaporization sprays of 2.5 per cent sulfadiazine solutions were employed, generally preceded by Vaponefrin sprays. Negligible blood levels were generally obtained. Defervescence, diminution in the amount of sputum and general clinical improvement followed. In a striking case, a woman in the seventies with bilateral chronic bronchiectasis and pulmonary emphysema was able to leave the hospital after a week's treatment. Previously, she had been confined for many months.

It is difficult to evaluate the specificity of such therapy in a limited series, but the observations by other investigators have also been extremely encouraging. It appears that in patients with chronic bronchiectasis, an ideal technic is the combination of the following: nebulization of a microcrystalline suspension of sulfathiazole,¹⁴ use of oral iodides to decrease the viscosity of the secretions, addition of iodine¹⁵ to the sulfathiazole solution as an oxidizing agent¹⁶ to help destroy the inhibitory effects of para-aminobenzoic acid present in purulent exudates, and periodic bronchoscopic drainage.

Tracheotomies²⁹ were performed on many of the victims of the Coconut Grove disaster. These victims generally presented the picture of progressive anoxemia and obstructive respiratory disease. Tracheal edema as well as pulmonary edema was evident. It was generally believed by various observers that this procedure was performed too often, and in many cases with disastrous results. No one can deny its indication in selected cases with tracheal obstruction above the suprasternal notch, but in victims of gas inhalation the fundamental involvement is largely pulmonary.

Tracheotomized patients generally demonstrate persistent pulmonary fluid loss through the tracheotomy tube. This requires aspiration and suction at frequent intervals. Physiologically this procedure is unsound. These patients have lost the back pressure against the pulmonary capillaries that they are accustomed to. If tracheotomy must be performed, one should keep the opening dry and clear and apply positive-pressure inhalation therapy with proper humidification through the tracheal cannula.

In general, then, it is best to attempt a program of positive pressure, preferably with the ventilated or pressure hood apparatus, using mixtures of helium and oxygen, before resorting to tracheotomy in cases of tracheal obstruction, whatever the cause. The number of tracheotomies is minimized in this way.

SUMMARY

Physiologic directed inhalation therapy in the management of a consecutive series of 49 cases of pulmonary or cardiac disease demonstrating anoxia, obstructive breathing or pulmonary edema alone or in combination has been described.

There were 12 deaths. Eight of these cases were proved to have been hopeless from the outset, and it is questionable whether the other 4 patients could have been saved by any method of therapy. Many of the recovered patients were moribund at the outset, and the clinical improvement and recovery were striking.

The management of such cases included the following: oxygen or helium and oxygen mixtures, with or without positive pressures as indicated, using the B. E. M. mask and hood apparatus; repeated bronchial relaxation by the use of rectal aminophyllin, Dilaudid, iodides and vaporization with Neo-Synephrin and Vaponefrin; both the foregoing were carried out simultaneously or in part alone, depending on the circumstances.

Certain physiologic objections to tracheotomy have been presented.

Inhalation therapy is a most important adjunct in the therapy of serious cardiorespiratory disease, and the principles and equipment necessary should be more widely disseminated.

ing cough became less severe and more productive; in the patients with bronchial asthma, the total pulmonary ventilation was reduced and the vital capacities promptly increased; in the patients with pulmonary edema, the diffuse moist rales disappeared or diminished as long as the positive pressure was applied or until the original cause was removed; and in the patients with tracheal or tracheobronchial obstruction, there was a marked reduction in respiratory effort, particularly in inspiration, and respiratory failure was averted. Two case histories follow:

CASE 4. A middle-aged man was suffering from severe tracheal obstruction following the removal of a massive colloid goiter. Anoxia, cyanosis and marked inspiratory effort were apparent and a tracheotomy was to be performed. Shortly after a trial period of helium-oxygen breathing with positive pressure, the respiratory distress diminished, and within a few hours all signs of anoxia and suprasternal obstruction disappeared. The patient made an uneventful recovery.

CASE 5. A 52-year-old man with a complete atelectasis of the entire right lung that came on during convalescence from a severe atypical pneumonia was successfully managed with a complete program of physiologically directed therapy. When first seen, he was in severe pain and in mild shock. Anoxia, cyanosis and rapid respiratory failure seemed imminent. Pure oxygen under positive pressure brought relief. After a short trial, a mixture of 75 per cent helium and 25 per cent oxygen was substituted without the patient's knowledge. The relief was even more striking. Thereafter, for a period of 2 weeks he was treated intermittently with helium-oxygen mixtures and oxygen. He was discharged home after 1 month. The lung was completely expanded after 6 weeks, and he was able to resume his normal activities.

Treatment

The type of gas mixture used in these cases depended on the factors responsible for the dyspnea, whether anoxemia or respiratory obstruction. If anoxia was the main factor, oxygen in concentrations of 95 per cent or more was used alone with either the B. E. M. mask or hood. If respiratory obstruction or bronchial spasm predominated, mixtures of 70 to 75 per cent helium and 30 to 25 per cent oxygen were found more beneficial. These mixtures are about one third as heavy as air. Barach²⁰⁻²³ and Behnke²⁴ have demonstrated that an 80 per cent helium and 20 per cent oxygen mixture is from 30 to 50 per cent easier to breathe through constricted orifices than is air. Dean and Visscher²⁵ later demonstrated that in going from air to helium and oxygen in the laboratory animal with tracheal obstruction, there was 40 per cent reduction in the work of ventilation. In obstruction extended in a linear direction, however, the above physiologic advantages are reduced by the slightly increased viscosity of helium above that of nitrogen. Hence, helium should *not* be considered a panacea for all types of difficult breathing.

The more localized the obstruction the greater was the immediate relief observed. The relief in patients with status asthmaticus or in those with bronchospasm associated with atypical pneumonia or inhalational gas poisoning was generally prompt

and lasting. The majority of the patients with bronchial asthma were adrenalin fast and had not responded to repeated intravenous injections of aminophyllin, oxygen and sedation with morphine and paraldehyde. The earlier cases in this series were treated continuously with helium-oxygen mixtures. The later cases were treated intermittently with comparable results. In a few recent cases, I have followed Barach's²⁶ suggestion employing mixtures of nitrous oxide, helium and oxygen and have observed very effective relaxation.

Positive-pressure therapy, with either oxygen or helium-oxygen mixtures, was effectively administered through the B. E. M. mask, which is metered for positive pressure up to 4 cm. of water in the expiratory phase only, or in the hood apparatus during both inspiration and expiration. The application of a gentle internal distending force served to keep the bronchioles patent and opposed the hydrostatic pressure within the capillaries.²¹

In the cases of pulmonary edema, positive-pressure oxygen was employed in the expiratory phase of respiration with the mask apparatus and found most effective. In the cases with severe bronchospasm, a positive-pressure helium and oxygen mixture was employed in both phases of respiration with the hood apparatus. The best effect on bronchospasm was observed in the inspiratory phase of respiration.

Generally, positive pressures of 2 to 6 cm. of water were sufficient for preventing or treating pulmonary edema, but higher pressures were sometimes necessary for short periods. Pressures above 6 cm. of water in some cases diminish the return flow of blood to the right side of the heart. Theoretically, shock may be considered a contraindication to positive pressure. No difficulty is usually encountered if the lower pressures are used, beginning with 2 cm. of water and cautiously increasing the positive pressure as needed.

Some patients found such therapy tiring when the mask was used, and an occasional semiconscious patient at first became alarmed with the seemingly increased expiratory-phase resistance. Reassurance and rest generally overcame this. Wangenstein drainage or Miller-Abbott intubation was employed successfully in a few cases. This was carried out in both the mask and hood apparatus. Free, productive coughing and belching may be inhibited somewhat if therapy is continuous, hence rest periods are necessary.

Repeated bronchial relaxation was accomplished by the use of rectal aminophyllin, Dilaudid,* iodides, nebulization with Neo-Synephrin and Vaponefrin and proper humidification. A similar program has been described by Barach^{8, 9, 27, 28} and others.^{6, 18, 19, 29} Such a program is particularly effective in combination with helium-oxygen positive-pressure therapy, and its effectiveness varies directly with

*Barach²⁸ has used Demerol in approximately 20 cases of bronchial asthma, with results better than those with Dilaudid.

Price⁴ recorded a study of 224 children who had had single or multiple convulsions and were cared for by him as a member of a medical group that performed most of the medical service in a small city. With the history of parents and family and the obstetric, neonatal and pediatric histories at his command, he was able to assign etiologic factors to the convulsions that seemed adequate in all but about 12 per cent of the patients. This compared with an incidence of idiopathic convulsions about twice as great in Peterman's series of children coming to him solely because of convulsions. It must be remembered, however, that experience shows that the younger the patient the more probable is an etiologic explanation. Since the details of ages or the two series are not given by either author, it may be that comparison between them is unfair.

Postconvulsive pathology was investigated by Zimmerman⁵ in the brains of 16 children dying soon after severe convulsions. In all, loss of nerve cells on a noninflammatory basis had occurred. The cortex was involved in all cases, and in many the central gray matter and cerebellar nuclei in addition. Many of the patients had infectious diseases at the time of the convulsions, but especially striking was the case of a six-month-old patient who died of anoxia and convulsions thirty hours after accidental incision of the diaphragm during nephrectomy for tumor. Autopsy revealed an extensive pneumothorax and a widespread loss of cells from the cortex histologically similar to that found in the other cases. Zimmerman considered the cell injury to have been caused by anoxia and to have been the result, rather than the cause, of the convulsions. In the light of his findings, it is incumbent on the physician to take measures to combat anoxia during convulsions.

Penfield and Erickson⁶ published an encyclopedic study of epilepsy the main thesis of which was that convulsions can be divided according to their manifestations into fifteen types, many of which can be related to various parts of the brain (Table 1). Such a classification was useful to them in attempting to localize lesions amenable to surgical attack. It also directed attention to the well-known but often forgotten fact that convulsive cerebral discharges are not necessarily accompanied by motor phenomena and that pain or special sensory or visceral sensations are often the expression of such a discharge.

Wechsler⁷ published a study of a series of cases in which abdominal pain was the presenting symptom of intracranial neoplasms or abscesses that could be localized. The lesions involved the frontal, temporal or occipital cortex or the cerebellum or brain stem. Wechsler called attention to the fact that the most frequent aura of epilepsy is abdominal pain or discomfort and that in many cases abortive attacks consist only of such an aura. He also sug-

gested that the pain of hysteria may be real pain on a psychosomatic basis, the result of actual changes in brain physiology.

Bridge, Livingston and Tietze⁸ reported a study of 83 children who were brought to the hospital suffering from breath-holding spells. The incidence of such spells in a clinic population was also investigated. It was found that there was no sharp division between simple tempers and breath holding, but

TABLE 1. *Types of Convulsions in Epilepsy (Penfield and Erickson⁶).*

CLINICAL TYPE	LOCALIZATION
Somatic motor manifestations:	
Generalized seizure (grand mal)	Complete motor area
Jacksonian (local motor) seizure	Prerolandic gyrus
Masticatory seizure	Lower rolandic area
Simple adverse seizure	Frontal area
Tonic postural seizure	
(decerebrate, opisthotonos)	
brain stem	
Somatic sensory manifestations:	
Somatosensory seizure	Postrolandic gyrus
Visual seizure	Occipital area
Auditory seizure	Temporal area
Vertiginous seizure	Temporal area
Olfactory seizure	Infratemporal area
Visceral manifestations:	
Autonomic seizure	Diencephalic area
Psychical manifestations:	
Dreamy state	Temporal area
Petit mal	
Automatism (ictal and postictal)	
Psychotic states (secondary)	

it was also true that in the children admitted with a complaint of breath holding the manifestations were much severer than in the clinic patients not complaining of them. A preceding circumstance arousing a violent emotional response was an essential part of a breath-holding spell, especially frequent causes being pain and anger. Following the stimulus the child sometimes took a breath or two, crying loudly, and then became rigid all over, holding his breath in expiration. In five or ten seconds cyanosis resulted, about twenty seconds caused severe cyanosis and unconsciousness with a fall to the floor, and thirty or forty seconds of breath holding usually resulted in convulsive phenomena, either generalized or localized. Following the attacks the children were confused or drowsy and more or less exhausted in proportion to the severity of the attack.

Follow-up studies were made on 51 patients at an average age of eleven years. The average age at onset had been about one year and the average age at recovery had been about four years, but there was a wide range. Practically all the children had outgrown the breath-holding habit by the time they were ready for the first grade. Mentally retarded children clung to the habit longer than did normal children. Of the 83 original patients, 3 had had recurrent convulsions prior to the breath-holding attacks, 2 had epilepsy when seen for follow-up, and 2 were thought to have it although the diagnosis was not absolutely proved. This represents an incidence of 8 per cent, a considerable increase over Thom's finding in his large group of unselected chil-

MEDICAL PROGRESS

EPILEPSY AND CONVULSIONS IN CHILDHOOD

RANDOLPH K. BYERS, M.D.*

BOSTON

SINCE no satisfactory method of differentiating so-called "simple convulsions" of childhood from epilepsy exists, it is necessary to consider together the entire group of convulsive disorders. A study by Thom¹ demonstrated clearly the close relation that exists between the two heretofore artificially separated groups. He made a comparison of the incidence of epilepsy over a period of years in 8000 unselected children first seen in a well-baby clinic and 395 children seen because of infantile convulsions. Of the former less than 1 per cent developed epilepsy during the follow-up period, whereas of the latter 12 per cent were definitely epileptic at the end of the study. In particular, Thom found that convulsions recurring over a period of weeks or months were likelier to be followed by epilepsy than was a single convulsion or a series of convulsions occurring within a relatively short period of hours or days. In his experience so-called "idiopathic convulsions" were likelier to merge into a chronic convulsive disorder than were those of any other group except those cases in which there was manifest brain damage. Petit-mal attacks occurring in the first two years of life were likely to merge into epilepsy or to become associated with mental retardation. Convulsions of themselves might cause cerebral damage affecting brain development and subsequent mental development. A bibliography of similar and related studies is appended to his article.

*Instructor in pediatrics, Harvard Medical School; associate visiting physician, Children's Hospital.

A study by Peterman,² also of a large group of children subject to convulsions, added evidence tending in the same direction. He pointed out that on electroencephalography a large percentage of such children showed what he interpreted as a cerebral dysrhythmia. Since standards for normal children of the younger age group have not yet been thoroughly evolved, it may be necessary to modify Peterman's figures, but there can be little doubt about the general conclusion, namely, that the cerebral physiology of children subject to convulsions is different in many cases from that of normal children.

On the other hand, evidence that the infantile nervous system responds to imposed stresses by convulsions more easily than the adult nervous system was obtained by Wegman.³ He elevated the body temperature of cats and kittens in a radiant-heat chamber and found that a rapid rise in body temperature was followed by convulsions much more frequently in kittens than in cats. A slow rise in temperature was seldom followed by convulsions. Neuropathologic changes were found that varied somewhat in relation to the rate of temperature rise. These findings suggested that convulsions may be produced in childhood by stresses that would be ineffective in adulthood. On the other hand, it may well be that neuropathologic changes can be produced either by the causative agent or by the convulsion itself, tending to lower the convulsive threshold in later life.

EDITH E. PARRIS, *Assistant Editor*

CASE 30421

PRESENTATION OF CASE

A thirty-one-year-old housewife entered the hospital because of pain in the abdomen and constipation.

The patient had been in apparent good health until ten days before entry, when she developed crampy, intermittent pain in the left lower quadrant of the abdomen. She passed no gas or feces by rectum despite repeated cathartics and enemas. She became increasingly anorexic, but had no nausea or vomiting. On the day before admission, after taking a liquid cathartic, she experienced severe pain in the abdomen, which required morphine. She had had an appendectomy five years before admission. She had always been somewhat constipated, but never had any rectal bleeding. The menstrual periods had been regular, the last period occurring three weeks before entry. There had been no weight loss.

Physical examination showed a well-developed, slightly obese woman, complaining of pain in the left lower quadrant. The heart and lungs were normal. A low, well-healed, midline abdominal scar was present. Two dilated loops of intestine could be seen running obliquely across the abdomen.

*On leave of absence

There was tenderness, with slight spasm, in the left lower quadrant, but no rebound or cough tenderness. Bursts of high-pitched peristalsis were heard accompanying the bouts of pain.

The blood pressure was 110 systolic, 60 diastolic. The temperature was 100°F., the pulse 86, and the respirations 22.

Examination of the blood showed a white-cell count of 12,000. The urine was alkaline, with a specific gravity of 1.012; 2 or 3 white cells per high-power field were seen in the sediment. A blood Hinton test was negative. A plain film of the abdomen showed a single loop of dilated large intestine, apparently extending up from the sigmoid. A small amount of gas was scattered through the remainder of the large intestine. A barium enema (Fig. 1) showed the barium to fill as far as the rectosigmoid junction, at which point there was a definite twist of the mucosa. A small amount of barium passed into the sigmoid, which was markedly dilated.

Shortly after admission an operation was performed.

DIFFERENTIAL DIAGNOSIS

DR. FRANCIS D. MOORE: This case at first glance, and indeed at second glance, looks fairly simple. For that reason it probably has some hidden hurdle. A thirty-one-year-old patient who had had intestinal obstruction for ten days came into the hospital. The question of which bowel was involved is of prime importance. We have good evidence that it was large-bowel obstruction. In the first place, she had been obstructed for ten days but was not extremely sick. In the second place, pain and obstipation had gone on for days without any nausea or vomiting. Both those facts suggest large-bowel rather than small-bowel obstruction. She had a severe bout of pain when she took a cathartic,

dren followed for a longer period. In addition, behavior disturbances were extremely frequent in this group of children. It thus appears that children subject to severe breath-holding spells tend to be less satisfactory subjects than do unselected ones, but that by and large their chances of developing serious aftereffects are small.

From the point of view of treatment, several of the previously mentioned articles give valuable suggestions. Peterman² pointed out that the convulsion per se tended to raise the body temperature, with possible damage to the brain, and that hence the time-honored hot bath, even though not hot enough to burn the skin, tended to increase the already rising temperature. He recommended cool sponging, sodium phenobarbital subcutaneously, chloroform or vinyl ether by inhalation, if needed in addition, and clearing the airway in acute emergencies. He considered a ketogenic diet the most effective treatment. He added that accurate diagnosis is essential for correct treatment.

Penfield and Erickson⁶ covered the treatment of convulsions and epilepsy thoroughly from both the medical and the surgical point of view; their book should be consulted for details. An important point mentioned by them was that morphine has extremely poor anticonvulsant properties and that since it is a respiratory depressant it may make the anoxia worse and is contraindicated in convulsions.

Price, Waelsch and Putnam⁹ described the usefulness of racemic glutamic acid hydrochloride in epilepsy associated with slow waves in the electroencephalogram, that is, in petit-mal and psychomotor attacks. It was ineffective in grand mal. The dosage was controlled by the reaction of the urine, an attempt being made to maintain it at a level of pH 4.5 to 5.0, as measured with nitrazine papers. Increased physical and mental alertness was a most gratifying result noted by parents, teachers and physicians.

Supplies of this drug are not as yet on the market, but it is being distributed through a few teaching hospitals. A small number of cases of petit mal treated at the Children's Hospital have shown marked reduction or suppression, and in most cases improvement in the patient's mental attitude and personality has been striking. The patients so treated are still small in numbers, and chance may well have been important in influencing the results.

Sodium diphenylhydantoin was introduced for the control of convulsions by Merritt and Putnam^{10, 11} after a series of experiments in the control of artificially induced convulsions in cats by a number of related compounds. They found it effective in a group of epileptic patients in whom other drugs had been useless. Petersen and Keith¹² found that of 59 patients previously treated unsuccessfully with phenobarbital or bromide, 8 per cent were completely relieved of their attacks, and another 61 per

cent were greatly improved both as to frequency of attacks and as to sense of well-being.

Lennox¹³ reviewed the drug treatment of epilepsy and concluded that diphenylhydantoin sodium (Dilantin sodium) is the drug of choice, both because it is more effective than other drugs in controlling attacks and because it is much freer from hypnotic effects than are the sedative drugs. In his experience it was most effective in psychic attacks, less so in grand mal and least effective in petit mal. He listed its toxic effects as gastric, dermatologic, gingival and neurologic. The unpleasant gastric symptoms were benefited by giving the drug after meals. The dermatitis was usually mild and tended to regress in the milder cases if the drug was temporarily discontinued and resumed in smaller doses, with a gradual increase to an effective level. Gingival hyperplasia was occasionally seen and caused little discomfort. It seemed not to be related to scurvy, as had been suggested. Neurologic disturbances, such as tremor and ataxia, could usually be controlled by reduction of the dosage, but in a few cases psychologic symptoms, such as hallucinations and maniacal states, tended to recur no matter how cautiously the drug was exhibited.

Regarding the actual use of the drug, Lennox pointed out that it is of the utmost importance, as with all other forms of treatment, to have an accurate record of the incidence of seizures before commencing it. In changing to this drug from one of the sedative drugs, he considered it important to reduce the dosage of the latter slowly over a period of weeks. He recommended beginning the use of diphenylhydantoin sodium at a level of 0.03 gm. ($\frac{1}{2}$ gr.) twice a day for children under four years, the initial dose for older children being progressively more up to 0.1 gm. ($1\frac{1}{2}$ gr.) three times a day for those of approximately adult size. The dosage was to be increased until the attacks were controlled or toxic symptoms appeared. In children of six the upper limit of dosage was about 0.4 gm. (6 gr.) daily, and at adult levels the upper limit was 0.6 gm. (9 gr.) daily. The drug was dispensed in 0.1-gm. ($1\frac{1}{2}$ gr.) and 0.03-gm. ($\frac{1}{2}$ -gr.) capsules. For those unable to swallow the capsules Lennox recommended mixing the powder from the capsules with a little cream to cover its bitter taste.

Lennox made a plea for honesty in the prescription of all drugs and their discontinuance unless they accomplished a definite reduction in seizures or an important psychologic improvement.

that there was visible peristaltic activity indicated in the sentence, "Two dilated loops of intestine could be seen running obliquely across the abdomen," simply indicates that the bowel was dilated enough to be seen through the abdominal wall.

The laboratory work is not too helpful. Evidently the patient was not particularly dehydrated, since the specific gravity of the urine was only 1.012 — another point suggesting large-bowel rather than all-bowel obstruction. It would be interesting to know what a guaiac or benzidine test on the stool contents showed.

To summarize, we have a thirty-one-year-old woman, who, without previous symptoms, developed the symptoms and signs of large-bowel obstruction. The most frequent cause of such a situation is carcinoma, and this ought to be regarded as carcinoma until good evidence shows it to have been due to something else. One might say that this patient was too young for a carcinoma. She was young, but about a year or so ago Dr. Cope discussed a case here in which a boy of fourteen had a colloid carcinoma in the region of the splenic flexure. Therefore, her age does not rule it out. The sclerosing annular type of carcinoma of the sigmoid can often cause obstruction as its first symptom, since bleeding may only be occult, and anal or rectal symptoms may be absent.

What other conditions could have given this history? A diverticulitis can obstruct the large bowel, but one would expect some story of large-bowel difficulty over a period of years. Also, it is unusual for obstruction to be a predominant feature in diverticulitis, an inflammatory sort of reaction generally being more prominent. An endometriosis of the large bowel may obstruct, but one would not expect to be told that the menstrual periods were ineffectual.

Can an extrinsic band obstruct the large bowel as it so often obstructs the small bowel? The answer is, No; simply because large-bowel peristalsis is usually powerful enough to overcome a benign cicatricial stenosis or extrinsic band. Occasionally, stenosis subsequent to lymphopathia venereum or radiation is obstructing, but we have no evidence for either in this case.

How about volvulus? That is a condition that can obstruct the large bowel. It certainly is unusual in a woman of thirty-one, and I have already said that I think this ought to be considered cancer until proved otherwise. But I think the x-ray studies have "proved it otherwise"; in fact, I believe that the x-ray films are pathognomonic of volvulus. The barium running up and coming to a sharp point strengthens the argument for volvulus, and as Dr. Schulz said, the barium picture itself suggests a twist. The other point, as I have already mentioned, is that the degree of dilatation is so great that one suspects a loop obstructed at both ends,

and volvulus and internal hernia are about the only situations that produce obstruction of bowel at both ends of the loop. So I believe that we have good evidence that this patient had a volvulus of the sigmoid, supposedly due to the chance twisting of a congenitally long sigmoid mesocolon.

CLINICAL DIAGNOSIS

Volvulus of sigmoid.

DR. MOORE'S DIAGNOSIS

Volvulus of sigmoid.

ANATOMICAL DIAGNOSIS

Volvulus of sigmoid.

PATHOLOGICAL DISCUSSION

DR. RONALD C. SNIFFEN: Dr. Scannell, will you say a word or two about the operation?

DR. JOHN G. SCANNELL: I helped Dr. Munro operate, and the findings that Dr. Moore foretold were found. At operation the bowel, as I remember it, was twisted two and a half times. It was large and edematous. It was reduced, and a complementary cecostomy was performed. Twelve days later, the sigmoid was resected.

DR. SNIFFEN: Dr. Munro removed about 24 cm. of sigmoid colon. Externally it looked quite normal, apart from slight dilatation. Internally it was intriguing in that a fold of mucosa and bowel wall protruded into the lumen, looking much like a venous valve. Kinking of the sigmoid had apparently occurred some time in the past, and following this, fusion of the adjacent peritoneal surfaces by fibrous adhesions, thus producing a permanent infolding of the wall.

DR. MOORE: What was the relation of this "valve" to the volvulus? Did it seem to have anything to do with initiating the twist?

DR. SNIFFEN: The "valve" was approximately in the middle of the segment of sigmoid. Of course, when we received the specimen, there was no volvulus and the dilatation had subsided.

Microscopically the bowel wall was normal.

CASE 30422

PRESENTATION OF CASE

A seventy-one-year-old retired physician entered the hospital because of abdominal pain.

The patient had been in good health until four years before entry, when he had a combined abdominoperineal resection for carcinoma of the rectum in a community hospital. He was well until about one year before admission, at which time, following several attacks simulating gall-bladder disease, a cholecystectomy was performed, which gave complete relief. He remained asymptomatic until three days prior to entry when, after a heavy

which is also characteristic of large-bowel obstruction.

Let us see the x-ray films.

DR. MILFORD SCHULZ: The striking thing about the plain film is the large loop of gas-filled bowel that seems to rise out of the pelvis and to taper off to a point at its lower margin. After the intro-

structed at both ends, making a so-called "trapped loop." The dilatation, which I estimate to approach 15 cm. in diameter, is way out of the range of even a markedly dilated portion of small bowel. There is some gas in this film, which I should guess is in the cecum. Do you agree with that, Dr. Schulz?

DR. SCHULZ: Yes.

FIGURE 1. Roentgenogram Following the Barium Enema.
Note the dilated sigmoid (retouched).

duction of barium by rectum (Fig. 1), we see this tremendously dilated loop of bowel rising out of the pelvis, and a narrow area in the midsigmoid where it looks as though the bowel had been twisted on itself.

DR. MOORE: Dr. Schulz does not want to make it too easy for me. The x-ray films fit in with the concept that this was primarily large-bowel obstruction. In the first place, the large size of the loop is thoroughly compatible with an obstructed loop of large bowel, especially if the loop was ob-

DR. MOORE: That is further evidence that this was large-bowel obstruction, because in small-bowel obstruction after ten days one would not expect to find any gas in the large bowel.

Other features of the history are more or less non-contributory and I shall not go over them in detail. The physical examination was most significant in that the record states that the patient did not look particularly ill, a finding, as previously mentioned, that is not compatible with ten days of complete small-bowel obstruction. The

that there was visible peristaltic activity indicated in the sentence, "Two dilated loops of intestine could be seen running obliquely across the abdomen," simply indicates that the bowel was dilated enough to be seen through the abdominal wall.

The laboratory work is not too helpful. Evidently the patient was not particularly dehydrated, since specific gravity of the urine was only 1.012 — a point suggesting large-bowel rather than small-bowel obstruction. It would be interesting to know what a guaiac or benzidine test on the fecal contents showed.

To summarize, we have a thirty-one-year-old man, who, without previous symptoms, developed symptoms and signs of large-bowel obstruction. The most frequent cause of such a situation is carcinoma, and this ought to be regarded as carcinoma until good evidence shows it to have been due to something else. One might say that this patient is too young for a carcinoma. She was young, it is about a year or so ago Dr. Cope discussed a case here in which a boy of fourteen had a colloid carcinoma in the region of the splenic flexure. Therefore, her age does not rule it out. The sclerosing intussusception type of carcinoma of the sigmoid can often cause obstruction as its first symptom, since bleeding may only be occult, and anal or rectal symptoms may be absent.

What other conditions could have given this history? A diverticulitis can obstruct the large bowel, but one would expect some story of large-bowel difficulty over a period of years. Also, it is unusual for obstruction to be a predominant feature in diverticulitis, an inflammatory sort of reaction generally being more prominent. An endometriosis of the large bowel may obstruct, but one would not expect to be told that the menstrual periods were ineffectual.

Can an extrinsic band obstruct the large bowel as it so often obstructs the small bowel? The answer is, No; simply because large-bowel peristalsis is usually powerful enough to overcome a benign cicatricial stenosis or extrinsic band. Occasionally, stenosis subsequent to lymphopathia venereum or radiation is obstructing, but we have no evidence for either in this case.

How about volvulus? That is a condition that can obstruct the large bowel. It certainly is unusual in a woman of thirty-one, and I have already said that I think this ought to be considered cancer until proved otherwise. But I think the x-ray studies have "proved it otherwise"; in fact, I believe that the x-ray films are pathognomonic of volvulus. The barium running up and coming to a sharp point strengthens the argument for volvulus, and as Dr. Schulz said, the barium picture itself suggests a twist. The other point, as I have already mentioned, is that the degree of dilatation is so great that one suspects a loop obstructed at both ends,

and volvulus and internal hernia are about the only situations that produce obstruction of bowel at both ends of the loop. So I believe that we have good evidence that this patient had a volvulus of the sigmoid, supposedly due to the chance twisting of a congenitally long sigmoid mesocolon.

CLINICAL DIAGNOSIS

Volvulus of sigmoid.

DR. MOORE'S DIAGNOSIS

Volvulus of sigmoid.

ANATOMICAL DIAGNOSIS

Volvulus of sigmoid.

PATHOLOGICAL DISCUSSION

DR. RONALD C. SNIFFEN: Dr. Scannell, will you say a word or two about the operation?

DR. JOHN G. SCANNELL: I helped Dr. Munro operate, and the findings that Dr. Moore foretold were found. At operation the bowel, as I remember it, was twisted two and a half times. It was large and edematous. It was reduced, and a complementary cecostomy was performed. Twelve days later, the sigmoid was resected.

DR. SNIFFEN: Dr. Munro removed about 24 cm. of sigmoid colon. Externally it looked quite normal, apart from slight dilatation. Internally it was intriguing in that a fold of mucosa and bowel wall protruded into the lumen, looking much like a venous valve. Kinking of the sigmoid had apparently occurred some time in the past, and following this, fusion of the adjacent peritoneal surfaces by fibrous adhesions, thus producing a permanent infolding of the wall.

DR. MOORE: What was the relation of this "valve" to the volvulus? Did it seem to have anything to do with initiating the twist?

DR. SNIFFEN: The "valve" was approximately in the middle of the segment of sigmoid. Of course, when we received the specimen, there was no volvulus and the dilatation had subsided.

Microscopically the bowel wall was normal.

CASE 30422

PRESENTATION OF CASE

A seventy-one-year-old retired physician entered the hospital because of abdominal pain.

The patient had been in good health until four years before entry, when he had a combined abdominoperineal resection for carcinoma of the rectum in a community hospital. He was well until about one year before admission, at which time, following several attacks simulating gall-bladder disease, a cholecystectomy was performed, which gave complete relief. He remained asymptomatic until three days prior to entry when, after a heavy

dinner, he had "an upset stomach." An attempt to use warm water as a laxative made him vomit once or twice. Some time later he developed pain in the right lower quadrant requiring morphine. The bowel movements, which had previously been normal, ceased entirely. There had been no recent weight loss. He was unable to take anything by mouth until the day of admission, when he retained sips of water. No other information was available.

The past history was otherwise noncontributory.

Physical examination showed a well-developed, well-nourished man in slight distress. The heart and lungs were normal. The abdomen presented scars of the gall bladder and combined abdominoperineal operations and a colostomy. There was a large, tender mass filling the right abdomen. The mass was somewhat dull to percussion.

The blood pressure was 152 systolic, 86 diastolic. The temperature was 97°F., the pulse 90, and the respirations 15.

Examination of the blood showed a white-cell count of 10,500. The nonprotein nitrogen was 70 mg. per 100 cc., and the protein 5.8 gm. The chloride was 87 milliequiv. per liter. A plain film of the abdomen showed dilated loops of small intestine in the midportion and left side of the abdomen. The cecum was filled with fecal matter, and there was a considerable amount of gas in the transverse colon and splenic flexure. No gas was seen in the region of the pelvis.

A few hours after admission an exploratory laparotomy was performed.

DIFFERENTIAL DIAGNOSIS

DR. GORDON A. DONALDSON: I might say at the outset that I shall accept the fact that this man had gall-bladder disease, perhaps stones and that he was completely relieved by cholecystectomy.

There are several points in the history, as you might guess, that I should like to have in order to make a diagnosis. I suspect that the patient was too ill to give any further points that might be helpful. The brevity of the physical examination, however, I am at a loss to explain. For instance, I should like to know about peristalsis. Too often the use of the stethoscope by the surgeon is overlooked. The absence or presence and type of peristalsis would be of tremendous help in this particular case. I should also like to know more about the nature of the mass in the right lower quadrant—whether it extended to the flank, whether it had an edge, and just how tender it was. It is merely stated that he had pain in the right lower quadrant. It would have been of help, I think, to have examined the patient through the colostomy to see if anything could be felt within the abdomen. I shall have to work, however, with what I have.

A few points are definite, and I must say that some of them disturb me. In the first place, the sequence of vomiting followed by pain is unusual.

I should guess that the vomiting was reflex in origin at the outset, starting in the region of the ileocecal valve. This went on into persistent vomiting as a result of small-bowel dilatation. Whatever the patient had, then, lay in the region of the ileocecal valve and later precipitated small-bowel obstruction.

The laboratory data are consistent with the history of three days' obstruction. I think the elevation in white-cell count was probably due to moderate degree of dehydration. The nonprotein nitrogen was slightly high, which can be explained on the same basis. The total protein was perhaps rather low, but the patient might well have had liver that was not functioning properly. The blood chloride level was consistent with the story of vomiting. As to the chart, the pulse was low for a degree of severe intestinal obstruction; the temperature was consistent with a noninflammatory process.

I think that we might gain a great deal by looking at the x-ray films.

DR. MILFORD SCHULZ: On this film you see several rather widely dilated loops of small bowel. There is no gas or feces in the distal half of the colon, but there is quite a bit of gas and fecal matter in the cecum.

DR. DONALDSON: There is more gas in the cecum than I had counted on; perhaps this can be accounted for by a self-administered enema.

Can you outline a mass?

DR. SCHULZ: I cannot see a definite mass in the abdomen.

DR. DONALDSON: Can you outline the liver edge?

DR. SCHULZ: No; it probably comes down to just above the splenic flexure, as indicated by the gas-filled bowel. One really cannot see the liver edge except in so far as the bowel is adjacent to it.

DR. DONALDSON: I should say that the small bowel is diffusely dilated to a rather severe degree.

DR. SCHULZ: Yes; curiously enough there is not a great deal of dilatation in the right lower quadrant, but the bowel may be filled with fluid and not evident.

DR. DONALDSON: The positive evidence in this case is disconcerting. In the first place, I doubt that the dilatation in the right lower quadrant was due to an inflammatory process. It is unlikely that the patient had had a vascular accident in the bowel, in view of the relatively low white-cell count and the type of pain. He could have had, of course, a retroperitoneal recurrence of malignant disease in the abdominal cavity; but that also is unlikely, although a possibility. It is strange that the physician noted a sizable mass in the right lower quadrant. From the x-ray film, I should guess that the liver as a source of this mass is ruled out.

We then come down to the fact that the likeliest cause for this mass is bowel. In any combined abdominal resection in which the upper sigmoid is not sutured to the lateral abdominal wall it is always possible for the bowel subsequently to herniate

through the opening in the left gutter and to go into the lower abdomen, possibly extending into the right abdomen. Such a condition is consistent with the x-ray findings. I must say that I am not too satisfied with that diagnosis because I could expect that there would have been more loops of small bowel in the right lower quadrant. Traction on the sigmoid the small bowel would cause obstruction distal to the splenic flexure, which would produce gas in the proximal large bowel.

DR. RONALD C. SNIFFEN: Dr. McKittrick, will you tell us about your findings.

DR. LELAND S. MCKITTRICK: First of all, I am clear what Dr. Donaldson's diagnosis is.

DR. DONALDSON: Bowel volvulus.

DR. MCKITTRICK: What do you mean by "bowel volvulus"?

DR. DONALDSON: I think that the bowel had herniated down through a trap in the left gutter, thus presenting itself in the right lower quadrant.

DR. OLIVER B. COPE: Do you mean the small intestine — a small-intestine volvulus? You made the statement that the bowel was distended to the splenic flexure.

DR. DONALDSON: I think that in rotating the small bowel produced obstruction in the colon.

DR. MCKITTRICK: I was greatly impressed and rather disconcerted by the confidence with which Dr. Donaldson anticipated seeing the x-ray films, because I rarely have any films shown to me at these conferences that do not add to my confusion. Something about them always seems to mix me up.

DR. DONALDSON: I was looking for help in the history.

DR. MCKITTRICK: And you did not get it.

DR. DONALDSON: No.

DR. SNIFFEN: Dr. McKittrick, can you answer any of Dr. Donaldson's questions?

DR. MCKITTRICK: I cannot. One of them was particularly pertinent. I am open to criticism because I did not listen with a stethoscope and consequently do not know whether the patient had peristaltic sounds. Dr. Moore probably did listen to the abdomen and can give an answer.

DR. FRANCIS D. MOORE: There was no evidence of peristalsis, but the patient had been obstructed for three and a half or four days.

DR. MCKITTRICK: There was a definite large mass filling the right lower quadrant, just as the transcript says. It was tender and surprisingly firm. Before these x-ray examinations I thought that the patient had an acute obstruction of the small bowel. Then when I looked at the x-ray films and saw the gas in the large bowel, it was a bit disturbing because it really did not fit in with what I thought the x-ray films should have shown. Since he had an acute illness of three days' duration, had passed no gas through the colostomy and had a tender mass in the right lower quadrant, it seemed to me that he had

a strangulated small bowel. I did not know quite how to explain the findings in any other way, and it was on that basis that he was operated on.

CLINICAL DIAGNOSIS (PREOPERATIVE)

Strangulated small bowel.

DR. DONALDSON'S DIAGNOSIS

Small-bowel volvulus.

ANATOMICAL DIAGNOSIS

Small-bowel volvulus.

PATHOLOGICAL DISCUSSION

DR. MCKITTRICK: At operation, when the abdomen was opened, which we did through a right incision, all one could see was strangulated bowel. The mass that we had felt was strangulated bowel, and I still do not understand how it could have been so firm. I believe that I have never felt intestine that was so firm and tense as this small bowel was. It was shiny and quite discolored. He did have a volvulus, and the lateral gutter was still obliterated. Dr. Donaldson was perfectly right: the patient simply had a twist of the small bowel at its mesentery, and there was a fixed point that had to be freed before it could be untwisted. We made an enormous incision — practically from one end of the abdomen to the other — in order to untwist the bowel without rupturing it. The color improved a bit as we watched it, and we put it back without any further manipulation because it seemed to me that there was no possibility of getting him by if we attempted major resection. We had to run the chance that this was viable bowel, even though we thought the prognosis was bad. At the end of operation the patient was in excellent condition.

DR. SNIFFEN: Do you believe that any of the adhesions from the previous operations initiated the volvulus?

DR. MCKITTRICK: I do not quite see how they could have. There was no definite point of obstruction because of a constricting band. Why the intestine had twisted is beyond me. There were a couple of fixed points, however, that probably had something to do with it. The interpretation of the mechanism of an acute small-bowel obstruction has always been a difficult thing for me, and I do not know just how to interpret this. We know that the gutter was still completely obliterated.

DR. DONALDSON: Is it not unusual to have that amount of gas in the large bowel?

DR. MCKITTRICK: Yes, but he may have taken an enema as you suggested. That would put air in the large bowel.

DR. SNIFFEN: This man died about ten hours after operation. The essential finding was early gangrene of the lower jejunum and upper ileum for a distance of approximately 250 cm. There was no acute

peritonitis, although about 300 cc. of blood-tinged fluid had spilled into the peritoneal cavity. The various loops were bound together by old fibrous adhesions. The mucosa was intact in the involved intestine, and the wall seemed viable, although it was deep red. Its mesentery was not long and measured only 12 cm., the average length of the mesentery of the small intestine being about 20 cm. The mesenteric arteries and veins were patent throughout. On microscopic section there was no definite histologic evidence of cell necrosis, although there was quite severe hemorrhage into the wall. There were extensive hemorrhage and edema in the lungs. We found no cancer, and the colostomy was in good repair.

DR. McKITTRICK: I do not quite know why this patient died. He was in surprisingly good shape at the end of operation, and although I thought

that he was going to die, I was surprised that he died so soon after operation.

DR. SNIFFEN: The pulmonary edema and hemorrhage were quite marked. We could find no obvious mechanical reason for the twist.

DR. McKITTRICK, in operating on volvulus, how often do you resect the loop at the first operation?

DR. McKITTRICK: If badly obstructed, one would not resect the loop unless the bowel was nonviable. In large-bowel volvulus an experienced surgeon, if the setup is just right, occasionally removes the involved bowel, but it adds to the risk of operation.

DR. SNIFFEN: Do you advocate removing it if there is an unduly long mesentery?

DR. McKITTRICK: We have done that not infrequently in large-bowel volvulus, but in most cases as an elective procedure after we have taken care of the mechanical obstruction.

MASSACHUSETTS, THERE SHE STANDS

THIS country has lapsed into that dangerous period of its long struggle for victory in which it has become overly war-weary; like a fighting team that has trained zealously and enthusiastically for its great effort, it has gone stale. We need not compare ourselves with England, two years longer at war than we have been, or with Russia, a year ahead of us in the conflict, or with China; after eight years of the struggle, or with Germany. The case is different; they have either been faced with doom from the beginning if they relaxed or, after tasting victory, have seen the inevitability of defeat gradually shaping itself.

The temperamental citizenry of our somewhat emotional nation has been too far from the thunder of the big guns. It has seen victory around each corner since the close of the campaign in North Africa, its natural, if somewhat immature, ebullience being daily stimulated by the eruptions of the pollyannas of press and radio, who dare not tell the truth lest the people become discouraged.

Each paean of triumph has had its damaging effect on the war effort. Fresh thousands have left the essential industries to find shelter in more permanent, if less lucrative, occupations; municipal solons are planning their several V-Day celebrations with the utmost gravity and in the minutest detail; G. I. Joe himself, we are told by certain of the less feverish correspondents, is becoming disheartened by the fact that all is not over, despite the prognostications of the armchair board of strategy. There has been too much talk about who gets home first when the war is over, and we are only now coming far enough out of Dreamland to realize that the war will not be over until the fighting stops, which may not be for a long time to come. Hitler could not have planned a better propaganda campaign to soften his forthcoming, if delayed, defeat.

A sign of the slackening war interest here at home that strikes close to the healing fraternity is the easy professional virtue that lends itself to an increasing prescription of extra rations for a self-indulgent public of doubtful patriotic fervor. Perhaps our sons and brothers before the Siegfried line or on the Pacific island beaches will die happier in the knowledge that Cousin Annie has had a slice of sirloin for her lunch or that Uncle Jim can have an extra bit of butter for his bread. No doubt an awareness, by their occupants, of the fact that fuel oil is flowing more freely on the Atlantic seaboard will make a few thousand dugouts on the western bank of the Rhine seem positively cozy this winter. Something more than medical necessity is needed to explain the certificates for extra rations that are being sent for review in this state, in addition to those granted by local boards, at the rate of a thousand a month.

God save the Commonwealth of Massachusetts!

CHEMOTHERAPY OF WOUNDS AND BURNS

In May, 1943, the Subcommittee on Surgical Infections of the National Research Council and the responsible investigators of the Contaminated Wound and Burn Project operating under the supervision of the Committee of Medical Research of the Office of Scientific Research and Development¹ presented before the American Surgical Association the results of a study on the prevention of infection in contaminated accidental wounds, compound fractures and burns. This report covered some 1500 cases collected subsequent to February, 1942.

Several points made in the introduction of the report are worthy of comment. A period of six months had elapsed between the time when the details of the plan of study were worked out and the time of its final adoption. The disaster at Pearl Harbor occurred before the work was started and apparently many of the participating investigators were persuaded to alter the proposed plan of study because of the report of observers who had returned from Hawaii. The latter had been profoundly impressed by the low incidence of wound infection, which they believed to have been due to the copious local application of sulfanilamide.

Not unnaturally, the judgment of these observers was greatly influenced by their enthusiasm and by the intensity of the dramatic aspects of their brief experience. Subsequently, more careful and deliberate observations apparently bore out the suspicion of many of the responsible investigators that the enthusiasm was not warranted or, at least, was premature and somewhat excessive. Fortunately, the scientific integrity of all the participants was beyond question, and the enthusiasm rapidly gave way to the tempered and deliberate judgment of the more conservative investigators.

The final results seemed to have justified this conservative attitude. The subsequent studies brought out many of the vital factors concerned in the development and persistence of infection in wounds and burns. The sulfonamides, used systemically, were found to minimize the general spread of infection and to cut down the incidence of sep-

ticemia and death. There was no evidence, however, that these drugs, with the methods employed—local, systemic or both,—produced any significant reduction in the incidence of local infection in the wounds. Thus, the report concludes, "we are going to lessen the incidence of local infections in war wounds and burns, some other form of the sulfonamides or some other bacteriostatic agents must be found which will be effective against the contaminating organisms in the presence of damaged tissue."

Since penicillin is active in the presence of damaged tissue, and, in effective amounts, is apparently not toxic to healthy tissues, this agent naturally presents itself as a possible logical answer to some of the objections raised in the report. Comment has already been made in this column concerning the experience of British investigators in England and in the Mediterranean area.² The concrete and practical results of these and other studies are now available in the form of a memorandum issued by the Medical Research Council.³ This memorandum gives the instructions prepared by the Penicillin Clinical Trials Committee for the use of penicillin in war wounds.

Studies on the use of penicillin in surgical infections in Army camps were reported by Lyons⁴ last winter. His report confirms the usefulness of penicillin in the treatment of wounds, even after they have become established, but he aptly emphasizes its role as a supplement in the overall surgical management of cases. He points out how the effectiveness of penicillin in controlling infection has aided the rapid re-establishment of a positive nitrogen balance, thus permitting the regeneration of hemoglobin and red cells in gunshot and other deep wounds. As in most similar therapeutic studies, the patients concerned probably received better and more skillful general care and attention than are afforded the average case with the same type of lesions. This must always be borne in mind in evaluating the merits of any agent or procedure.

The difficulties of evaluating drug treatment in surgical infections have recently been reviewed by Meleney,⁵ an investigator whose extensive studies in the field make him particularly well qualified to discuss this subject. He points out the numerous

persons involved in surgical infections, in contrast to those in other infectious diseases or what he calls "medical infections." The importance of weighing and measuring all these factors makes the appraisal of drugs in surgical infections infinitely more difficult than it is in most medical infections, and these difficulties apparently apply to penicillin as well as to the sulfonamide drugs.

CORRESPONDENCE

CIVILIAN NEEDS FOR WHOLE-BLOOD TRANSFUSION

To the Editor: Emergency situations when a blood transfusion is needed without delay have a way of occurring regardless of time, traffic or the vagaries of New England weather. Despite the stopgap that commercially available plasma fluids, the war has emphasized the superiority of whole blood. Yet often hours pass before even donors of known types are cross matched and the blood administered. Hemorrhage is just as serious in a civilian automobile casualty or a new mother as it is in a serviceman.

Is it not high time to utilize public interest and good will in saving the life of a neighbor in the postwar world? Even he's self, one's wife or one's child may be the victim.

All servicemen have been typed. Most civilians are anxious to know their own blood types. They are anxious to donate to blood banks since learning that they need fear no effects. If physicians can organize the activities, the people have shown they will co-operate. Local community donor lists at least could easily be arranged.

We now have the techniques, equipment and trained personnel in the large Boston hospitals. The small hospitals should have access to the services of state, municipal or Red Cross supported centers with twenty-four-hour telephone and motor-transport service for blood, plasma or donors available to all doctors on request. Patients could be charged according to their incomes.

Central blood-collecting and typing centers in Boston, Worcester and Springfield need but the stimulus of the Massachusetts Medical Society to portray the need by press and radio.

No one knows how long the war will last. It is not, however, too early to plan to prevent needless loss of life on the home front now.

 Lieutenant Commander (MC), U.S.N.R.

EMIC PROGRAM

To the Editor: I have just read your editorial in the September 7 issue of the *Journal* entitled "Massachusetts EMIC Program" and because to me it appears that there are perhaps some phases of this program that you do not fully understand I am taking the liberty of writing to you about this matter.

While I am agreed that it is desirable to free from worry the men in the armed service regarding the proper care of

their family, — provided that these men are subject to worry because of financial handicaps, — I cannot agree that the method chosen is either wise or proper. Many of the men in the lower four pay grades are amply able to provide adequate medical care for their wives. However, if it be argued that all of these men should be treated alike, regardless of financial status, then we would contend that each be given a definite sum of money for such care, the amount to be fixed by Congress, and that these men then be permitted to expend this money for service as they elect.

Some may want hospital care and a private nurse and a specialist to attend the wife, some may want a home delivery by the family doctor, and still others may want ward care in the hospital. In either case they would be able to elect the type of care that best suits their condition, whereas under EMIC each must accept ward care in a hospital and a doctor whose fee does not deter him from accepting such cases. And if a doctor cannot be induced to sign up for the case, then hospitalization is not available.

This plan would avoid the regimentation of the doctors, which to us is the most objectionable feature of the EMIC program.

I would also respectfully call your attention to the statement "according to the Children's Bureau, it will terminate six months after the war is ended." In fact this means that no new cases will be signed up after six months after the war is ended, but all cases signed up prior to this time will be carried to completion, and since the program provides care for the mother for six weeks after the delivery, and care of the infant for one year after birth it will be seen that the program will not end for more than two years after the end of the war.

Your attention is also directed to the new regulations of the Children's Bureau, which provide that after a doctor has signed up to care for an expectant mother he is thereby obligated to render to her every service that can be rendered in his office, regardless of whether or not it be connected with pregnancy. And the pay for all of this service is included in the one fee which he may collect. To take an extreme case, but one which might well occur: A doctor signs up to provide care for an expectant mother and during the pregnancy she suffers a fractured humerus, or similar accident, which he treats. She later goes to another city where she is delivered. The doctor who gave her the prenatal care may collect a maximum of fifteen dollars for prenatal care, including the care of the fractured humerus, provided she made seven visits to his office for prenatal care. If she made less than seven visits he must deduct two dollars for each office visit less than seven, and this without regard to her ability to pay for medical care.

This EMIC program has received rather close study by the Maternal and Child Health Committee of the Nebraska State Medical Society, of which committee I happen to be a member, and our committee has not enthused about the provisions of the program at any time, and are perhaps less enthusiastic about it since the promulgation of the new rules. Nor have many of the Nebraska physicians enthused about the program when they understood it.

It is our experience that the most ardent supporters of the program are those who have least understood it, whereas those who have given it close study almost universally feel that it is simply a foot in the door for state medicine.

In closing may I say that this letter is not meant to be critical of the *Journal* or its editorial staff. I have a very high regard for the *Journal* as evidenced by my being a subscriber for more than twenty-five years, but it is simply intended to explain why some doctors do not approve of the EMIC program and why they fear the influence of the Children's Bureau as the personnel is now constituted.

In determining whether or not this is a good type of medical care "as a steady diet" I feel that the paramount issue is whether or not it is a good thing for the sick patient. If we should decide that it is, we should lend our support to its extension; if we believe that it is not, then we should try to educate the public to its dangers and shortcomings, because in the final analysis whatever is good for the man who is ill, regardless of its effect on the doctor or the politician, is the type of medical care toward which we must aim if we are to do our full duty to posterity.

I hope that I have made clear my position with regard to the EMIC program. I have no criticism for those whose views may differ from mine.

G. E. PETERS

Randolph, Nebraska

The following resolutions were adopted at a meeting of the American Pediatric Society, held in Atlantic City, New Jersey, on September 26:

Whereas the objectives of the American Pediatric Society and those of the Children's Bureau concern the betterment of the health and welfare of the children of America, any break in the hitherto good relation of the two organizations would be harmful to the ends desired.

Whereas cash grants under the EMIC program would negate one of its principal purposes and would establish a dangerous precedent, and whereas all medical care for mothers and children under the Social Security Act, Title V, was designated in 1935 by Congress to be given on a service basis rather than as cash grants, a change in the method of payment in the EMIC program is not warranted or desirable.

Whereas the Miller Bill, now before Congress, advocates the transfer of the Health Services of the Children's Bureau to the United States Public Health Service, and in so doing would separate medical care from the other essential aspects of child care, and whereas the Miller Bill does not make any provision for the development of a National Department of Health, the American Pediatric Society feels that the transfer advocated in the bill is undesirable.

Whereas it is desirable to assemble facts and develop considered opinions on postwar planning for children before the meeting of the American Academy of Pediatrics in November, the American Pediatric Society requests that the American Academy of Pediatrics authorize its special committee on the EMIC program or another specially appointed committee to confer with a committee of three appointed by the American Pediatric Society and three members of the Medical Advisory Committee of the Children's Bureau and that this joint committee submit a report to the American Academy of Pediatrics at its November meeting.

Since these resolutions were adopted by a group whose members are well acquainted with the EMIC program, they serve to refute certain of the arguments raised in Dr. Peters's letter. — Ed.

DEPRIVATION OF LICENSES

To the Editor: At a meeting of the Board of Registration in Medicine held September 13, the Board voted to revoke the license to practice medicine of Dr. Mary E. Bolger, 442 Cambridge Street, Worcester, because of the violation of her probationary period as of February 10, 1942.

H. QUIMBY GALLUPE, M.D., Secretary
Board of Registration in Medicine

State House
Boston

To the Editor: At a meeting of the Board of Registration in Medicine held September 13, the Board voted to revoke the license to practice medicine of Dr. Don D. Cornell, American Hospital, Picher, Oklahoma, because of the violation of the Narcotic Act.

BOOK REVIEWS

Backache and Sciatic Neuritis: Back injuries — deformities — diseases — disabilities. By Philip Lewin, M.D. Line drawings by Harold Laufman, M.D. 8°, cloth, 745 pp., with 235 illustrations. Philadelphia: Lea and Febiger, 1943. \$10.00.

This book was written expressly to familiarize general practitioners with the problem of back pain. It can be said that the subject has been covered from the standpoint of terminology and that the text also includes most of the described syndromes known to the profuse literature on backache. Since there exist differences of opinion among authorities and since empiricism holds sway over scientific evi-

dence, the subject is difficult, but is fairly dealt with by the author. On the other hand, because the information in the book is a maze of generalities, the practitioner, although aware of more facts, is none the better prepared to reach a conclusion in a given case, either concerning diagnosis or treatment. Analysis of a given case is the keynote throughout yet no basis for the analysis is given; instead, the reader is many expressed viewpoints without critical reasoning to judge the good from the bad and is therefore apt to be left confused rather than clarified. On the whole, the book represents a tremendous amount of time in preparation, and the reviewer believes that the most valuable contribution is its extensive bibliography.

The Arthropathies: A handbook of roentgen diagnosis. Alfred A. de Lorimier, M.D. 8°, cloth, 319 pp., with 171 illustrations. Chicago: The Year Book Publishers, Incorporated, 1943. \$5.50.

The clinical and grosser roentgen features of the arthropathies are presented in usable tabulated form, abundantly illustrated by negative prints. This should be helpful to medical students, general practitioners and those whose diagnostic method is more clinical than roentgenologic.

The factual presentation is accurate, but caution may be advised in considering the theoretical explanations of the facts. The section on the spine falls below the standards attained elsewhere in the book.

The conditions included under the various group diagnoses are not synonymous, although they are listed under the heading "synonyms."

The meaning of the descriptive terms is not always entirely clear and the terms are rather broad in their application. For this reason the list of roentgenologic features for one diagnostic group may appear similar to those for another group.

The illustrations have been made from good films, but much detail has been lost in reproduction.

Medical Parasitology and Zoology. By Ralph W. Naus, M.D., Dr.P.H. With a foreword by John C. Torrey, Ph.D. 8°, cloth, 534 pp., with 95 illustrations and 15 tables. New York: Paul B. Hoeber, Incorporated. 1944. \$6.00.

The subject matter of this book is divided into four parts: the first of which deals with protozoa parasitic in man, the second with worms parasitic in man, the third with arthropods and disease transmission, and the fourth with poisonous and venomous animal life, including insects, coelenterates, mollusks, fishes, biting water bugs, snakes and lizards. In addition, the appendices contain valuable sections on the care and use of the microscope, methods for study and diagnosis of parasitic infections and summaries of the distribution and numbers of species of elapid and viperid venomous snakes of the nearctic and neotropical regions. The glossary includes a classification of animal parasites and arthropods and a helpful section of pertinent definitions. A bibliography and a subject index are provided.

The parasites are usually discussed under headings of geographical distribution, morphology, life cycle, epidemiology, pathology, symptomatology, diagnosis, treatment and prophylaxis. The bionomics and epidemiologic aspects of the more important species are not adequately dealt with to meet the needs of either student or practitioner, and seemingly contradictory statements will probably create some confusion. For example, on page 179 the reader is led to believe that the miracidium of *Clonorchis sinensis* does not hatch outside the molluscan host. On the following page, however, hatching of this miracidium is graphically illustrated in Figure 45, and it is stated, "In water it escapes through the opercular end of the egg to seek a suitable snail host."

The names *Oxyuris* and *Trichocephalus* are listed in the glossary as synonyms of *Enterobius* and *Trichuris*. The manner in which they are cited, however, *Enterobius (Oxyuris) vermicularis* (page 137) and *Trichuris (Trichocephalus) trichiura* (page 141) brings them into subgeneric rank, according to the International Code of Zoological Nomenclature.

The verbal descriptions of important parasites, particularly of the parasitic protozoa, and the tabular data on differential diagnoses are well done, with the desired information made readily available. Unfortunately, Figure 2 (gran-

entiation of amebae) is poorly executed and gives an erroneous conception as to the relative size of the species illustrated.

The book has greater value as a laboratory aid than as a text. The format is pleasing.

BOOKS RECEIVED

The receipt of the following books is acknowledged, this listing must be regarded as a sufficient return for the courtesy of the sender. Books that appear to be of particular interest will be reviewed as space permits. Additional information in regard to all listed books will be gladly furnished on request.

Birth Without Fear: The principles and practice of natural childbirth. By Grantly Dick Read, M.D. (Camb.). Cloth, 259 pp. New York and London: Harper and Brothers, 1944. \$2.75.

This manual has been written primarily for expectant mothers. It advocates education and preparation during months of pregnancy, with the belief that the mind and body will be relaxed to an extent that will materially lessen discomforts of childbirth. The author believes that fear is the part of the expectant mother has much to do with during labor. The book discusses the anatomy, physiology and psychology of birth, emphasizing the emotional and mental aspects. It should prove interesting to physicians, nurses and psychologists, as well as to mothers.

Textbook of Dermatology. By Norman Tobias, M.D., senior instructor in dermatology, St. Louis University, assistant dermatologist, Firmin Desloge and St. Mary's Hospitals, visiting dermatologist, St. Louis City Sanitarium and St. Louis Hospital. Second edition. 12°, cloth, 497 pp., with 110 illustrations. Philadelphia: J. B. Lippincott Company, 1944. \$4.75.

The second edition of this manual, first published in 1941, has been revised and brought up to date, still keeping the scope of the book within its original limits. The latest accepted treatments are described and the obsolete ones have been deleted. Brief descriptions of the rare dermatoses are included in this edition for the sake of completeness.

Textbook of Nutrition. A symposium prepared under the auspices of the Council on Foods and Nutrition of the American Medical Association. 8°, cloth, 586 pp. Chicago: American Medical Association, 1943. \$2.50.

This is a collection of papers on various aspects of nutrition specialists in their particular fields.

Arthus's Philosophy of Scientific Investigations: Facet de l'aphylaxie à l'immunité Paris (1921). Translated from the French, with an introduction, by Henry Sigerist, M.D., foreword by Warfield T. Longcope, M.D. Cloth, 26 pp. Baltimore: The Johns Hopkins Press, 1943. 75 cents.

This translation of a historically important article was first published in the October, 1943, issue of the *Bulletin of the History of Medicine*. It is now issued separately in bound form. It originally preceded the text of Arthus's book on aphylaxis and immunity. It was addressed to the author's physician and is a bit of medical literature that is worthy of being preserved and should be in all medical and scientific libraries. In its own way it compares favorably with the celebrated introduction to the study of experimental medicine of Claude Bernard, although Arthus's article is limited to a comparatively few pages.

Occupational Lead Exposure and Lead Poisoning. A report prepared by the Committee on Lead Poisoning of the Industrial Hygiene Section of the American Public Health Association. 8°, paper, 67 pp. New York: American Public Health Association, 1943. 75 cents.

This is a timely up-to-date monograph on an important problem in industrial medicine. The first three parts have to do with industrial lead exposure, and therein are discussed the recognition of the hazard, the safe limits of exposure and the control of exposure. This is followed by a chapter on occupational lead poisoning, in which diagnosis is stressed and the various types are described. The monograph concludes with a short discussion on management and treat-

ment. A valuable bibliography on the subject is appended to the text.

Studies from The Rockefeller Institute for Medical Research. Reprints. Volume 124. 8°, paper, 626 pp., illustrated. New York: The Rockefeller Institute for Medical Research, 1943.

The Medical Clinics of North America: Cardiovascular and blood diseases. Chicago number: January, 1944. 8°, cloth, 289 pp., with 37 illustrations and 8 tables. Philadelphia and London: W. B. Saunders Company, 1944. \$3.00.

Intravenous Anesthesia. By R. Charles Adams, M.D., C.M., M.S. (anes.), associate in Section on Anesthesiology, Mayo Clinic, instructor in anesthesiology, Mayo Foundation for Medical Education and Research, Graduate School, University of Minnesota, Rochester, Minnesota. 8°, cloth, 663 pp., with 75 illustrations. New York: Paul B. Hoeber, Incorporated, 1944. \$12.00.

This treatise comprises a comprehensive review of the use of intravenous anesthesia from its inception until the present time. All the available literature on the subject has been consulted. All the drugs that have been administered intravenously to produce anesthesia, as well as the various methods that have been employed and the results obtained from them, have also been reviewed. A chapter on intravenous anesthesia in military surgery closes the book.

Barometric Pressure: Researches in experimental physiology. By Paul Bert, M.D. Translated from the French by Mary Alice Hitchcock, M.A., and Fred A. Hitchcock, Ph.D., associate professor of physiology, Ohio State University. 8°, cloth, 1055 pp., with 89 illustrations, 23 tables and frontispiece. Columbus, Ohio: College Book Company, 1943. \$12.00.

In 1878, Dr. Bert published his classic text on the effects of barometric pressures on man. This translation is welcomed at this time when it can be of service to investigators in the field of aviation medicine. Dr. Bert was a pioneer in his field, and his work on the physiology of altitude is of much value today. His application of Dalton's concept of partial pressure to human respiration became the basis of all subsequent work in the field of altitude physiology. The original French edition is a scarce book, and the translators should be thanked for providing an English edition at this time.

Intracranial Arterial Aneurysms. By Walter E. Dandy, M.D., adjunct professor of surgery, Johns Hopkins University. 8°, cloth, 147 pp., with 55 illustrations and 7 charts. Ithaca, New York: Comstock Publishing Company, Incorporated, 1944. \$2.50.

This special monograph reflects the experience of the author in the diagnosis and surgical treatment of intracranial arterial aneurysms, with a record of 20 cured patients. The work is well illustrated and detailed charts containing complete information are appended to the text. There are 37 cases of aneurysms of the internal carotid artery, 25 of the anterior cerebral and anterior communicating arteries, 22 of the middle cerebral artery, 2 of the posterior cerebral artery, and 21 of the vertebral and basilar arteries. There is also an extensive bibliography.

The Management of Neurosyphilis. By Bernard Dattner, M.D., Jur.D., associate clinical professor of neurology, New York University Medical College. With the collaboration of Evan W. Thomas, M.D., assistant professor of medicine and assistant professor of dermatology and syphilology, New York University Medical College; and Gertrude Wexler, M.D., instructor in dermatology and syphilology, New York University Medical College. With a foreword by Joseph E. Moore, M.D., associate professor of medicine and adjunct professor of public health administration, Johns Hopkins University, physician-in-charge, Syphilis Division, Medical Clinic, and visiting physician, Johns Hopkins Hospital, Baltimore, and special consultant, United States Public Health Service. 8°, cloth, 398 pp., with 7 illustrations, 27 tables and 4 charts. New York: Grune and Stratton, 1944. \$5.50.

This special work is based on an experience of more than twenty years in dealing with neurosyphilis in its many aspects. The plan adopted in this work is similar to that used by the author in a similar book, written in Vienna in 1933. The work is divided into two parts: the first on the examination, the interpretation and the evaluation of the spinal fluid; and the second on methods of treatment. A comprehensive bibliography is attached to the text.

Harofé Haiori: Symposium on war medicine. In two volumes. Edited by Moses Einhorn, M.D. 8°, paper; Vol. I, 238 pp., and Vol. II, 223 pp., illustrated. New York: The Hebrew Medical Journal, 1943.

In these two volumes are included a number of articles on the surgical aspects of war medicine. In addition there are three articles on Palestine and the war. A 20-page dictionary of medical terms in Hebrew and English appears in Volume II. The text is printed in Hebrew and English.

Tuberculosis of the Ear, Nose and Throat: Including the larynx, the trachea and the bronchi. By Mervin C. Myerson, M.D., 8°, cloth, 291 pp., with 88 illustrations. Springfield, Illinois: Charles C Thomas, 1944. \$5.50.

This up-to-date manual is based on the personal experience of the author and is designed for the use of the otolaryngologist and bronchoscopist. Particular consideration has been given to tuberculosis of the larynx, trachea and the bronchi, where newer knowledge has been revealed by the bronchoscope. Diagnosis, prognosis and treatment are clearly described, based on the author's experience with over 10,000 tuberculous patients. The book is well printed on good paper, and well illustrated. Selected bibliographies are appended to each chapter.

On Growth and Form. By Sir D'Arcy Wentworth Thompson. 8°, cloth, 1116 pp., with 555 illustrations and frontispiece. New York: Macmillan Company, 1943. \$12.50.

This reference book was first published in 1917 during World War I and quickly went out of print. It has been carefully revised, reset, and considerably enlarged, giving the author solace and occupation when he was debarred from war service by his age. The book deals with the biologic problems of growth and form, and form and function in their necessary relation to physical principles and mathematical laws. The treatment of this complicated subject is simple; the physics and mathematics are elementary but comprehensive enough to throw light on fundamental problems of biology. This treatise on its subjects takes in material in botany, zoology, cytology, anthropology, mathematics, physics, chemistry, engineering, psychology and aesthetics.

Civilization and Disease. By Henry E. Sigerist, M.D., D Litt., LL.D., William H. Welch Professor of the History of Medicine, Johns Hopkins University. 8°, cloth, 255 pp., with 52 illustrations. Ithaca, New York: Cornell University Press, 1943. \$3.75.

In this book Dr. Sigerist has traced the varied and multiple influence of disease on every aspect of civilization. The work is based on a series of six Messenger Lectures, delivered at Cornell University in 1940, and expanded into a volume of twelve chapters. The first chapter on civilization as a factor in the genesis of disease is followed by chapters on disease and its relation to economics, social life, law, history, religion, philosophy, science, literature, art and music. In the final chapter, "Civilization against Disease," the author briefly reviews the advance of public health and its prospects for the future.

Studies from The Rockefeller Institute for Medical Research. Reprints. Volume 125. 4°, paper, 607 pp., illustrated. New York: The Rockefeller Institute for Medical Research, 1944.

Medical Diagnosis: Applied physical diagnosis. Edited by Roscoe L. Pullen, M.D., instructor in medicine, Tulane University of Louisiana School of Medicine, and assistant clinical director, Charity Hospital of Louisiana at New Orleans. With a foreword by John H. Musser, M.D., professor of medicine, Tulane University of Louisiana School of Medicine, and senior visiting physician, Charity Hospital of Louisiana at New Orleans. 8°, cloth, 1106 pp., with 584 illustrations and 12 colored plates. Philadelphia and London: W. B. Saunders Company, 1944. \$10.00.

This new work on medical diagnosis has been written on the premise that the scope of the subject has undergone sweeping changes and that for this reason a new work is justified. The author advocates complete examination of a sick person rather than a partial scrutiny of special symptoms and conditions. The work is divided into two parts, the first concerns the principles of physical examination, containing the procedures for examination of the patient as a whole. The second

has to do with special examinations, and here will be found chapters on psychosomatic medicine, mental measurements, electroencephalography, physical diagnosis of children, sterility surveys, occupational injury and military problems.

NOTICES

NATIONAL COMMITTEE FOR MENTAL HYGIENE

The thirty-fifth annual meeting of the National Committee for Mental Hygiene will be held on November 8 and 9 at the Hotel Pennsylvania in New York City. The decision to have a two-day annual meeting this year was prompted by the unusual opportunity and challenge to mental hygiene inherent in war activities, and in reconstruction and rehabilitation after the war. Topics for the various sessions will include the following: "Mental Hygiene of Industry and Reconversion"; "Rehabilitation and the Returning Veteran"; "Race Relations"; and "Services to the Mentally Ill Today." Various aspects of these topics will be discussed by persons of experience and influence in the various fields, and at each session about half the time will be reserved for discussion from the floor.

STUDIES IN MEDICAL SOCIOLOGY

II. The Relation of Mental Disorders to Population Density

MAJOR ROBERT W. HYDE, M.C., A.U.S., AND SERGEANT LOWELL V. KINGSLEY, A.U.S.

BOSTON

IN THE preceding study showing the relation of mental disorders to community socioeconomic level, variations in the rates of certain mental disorders were attributed to differences in population density. The purpose of the present study is to show these variations and to present possible explanations. Although there has been extensive investigation of rural-urban differences,^{1, 2} there has been no psychiatric study of an unselected cross section of the population. Previous work has usually been based on mental-hospital admissions and delinquency rates. Studies of this type do not eliminate the selective factor involved in local differences in attitude toward hospitalization and law enforcement.

Another weakness of rural and urban studies is the failure to make any correction in the findings for differences in socioeconomic level; hence, it has been difficult to isolate the rural-urban differences that are due to the differences in population density per se and not to the differences in economic level.

The examination of men coming to the Boston Armed Forces Induction Station from both rural and urban communities offers an excellent opportunity for the study of an unselected group of the male population. The communities sending selectees here have been classified regarding index of socioeconomic level according to grades of desirability, explained in more detail in other studies.^{3, 4} Since the relation of mental disorders to desirability level has been demonstrated,⁴ it is possible to make a correction for that factor and hence to approach the relation between mental disorders and population density.

One of the most significant studies of the relation of mental disorders to population density is that of Dayton,⁵ who found that, although 7.6 per cent of the population of Massachusetts is rural, only 3.9 per cent of first hospital admissions for mental diseases in Massachusetts were from rural environments. Mental disorders in patients from

rural environment were largely those associated with physical conditions, — namely, senile psychoses, mental deficiency, Huntington's chorea, somatic disease and arteriosclerosis, — whereas the most frequent abnormalities from the urban communities were paranoia, manic-depressive psychoses and psychoneurosis.

Shaw et al.⁶ found that delinquency rates dropped rapidly from the densest center of Chicago toward the least dense periphery, regardless of the nationality at the center, and like findings have been shown for Boston by the Boston Council of Social Agencies.⁷ In the examination of men drafted in World War I, mental deficiency was seen to be highest in rural areas, and other mental and nervous disorders and chronic alcoholism were higher in urban areas.⁸ These latter findings, although highly significant, are based on a far less extensive psychiatric examination than that done for the induction of men into the armed forces in World War II.

METHOD OF STUDY

The present study considers the same men as did that of the previous study of socioeconomic level, namely, those selectees from the eastern segment of Massachusetts examined at the Boston Induction Station during the winter, spring and summer months of 1941 and 1942.

The area includes a population distribution that is densest in Boston and includes 4 other cities of over 100,000 population, 5 with more than 50,000, 9 with more than 25,000 and over 50 towns and villages each with a population less than 2000. The sparsely populated areas represented are those of Cape Cod, the region inland from the southern coastal cities of New Bedford and Fall River and the region above the large cities immediately north of Boston.

Although the population is predominantly urban, the rural population is sufficient to be of significance. It is difficult to obtain any greater diversity of population densities than is present here and at

the same time to have all selectees examined at the same induction station, by the same criteria and by the same team of examiners. Because of the uniformity of the examinations on which the present study is based, it is possible to avoid the criticism made in connection with the World War I study of rural-urban comparisons that a large part of the differences is probably due to the more critical examinations made by the physical examiners in the large cities.⁹

Although the rating of density according to population per square mile does not always indicate the extent of overcrowding because of the occasional presence of densely populated and sparsely populated areas within the same community, it serves the purpose of a community study of this type. A more intensive study of density would take into consideration the average number of people per room and the proportion of uninhabitable land in any area.

In order to interpret properly the significance of our findings on the relation of mental disorders to population density, several factors related to density will be mentioned in the course of the explanation so that findings more closely associated with these related factors will not be falsely attributed to density. These factors are socioeconomic level, national origin, gravitation and ascent, selective migration and heredity.

Socioeconomic level has previously been shown to have considerable influence on the rate of psychiatric disorders. In the previous study all communities were rated according to medical, educational and recreational facilities, "class," public works, housing and welfare rates, and grouped into six categories of desirability, with A the rating for the best communities and F that for the poorest.

The *national origin* of people in a community, as shown by the proportion of people from certain nationalities, seems sufficient to account for variations in rates of mental disorders. There is considerable difference in distribution, with the Irish, Italians and Russian Jews the major elements in some of the large cities and French Canadians and Portuguese in others, with higher proportions of Old Americans in many of the suburban and semirural areas.

There is *gravitation* of the inadequate to the poorer communities and *ascent* of the ablest into the better communities.

Selective migration is that of the adventurous rural youth to urban areas.

Heredity is a difficult factor to measure, but is closely allied with density because of the fact that marital choice is more limited in areas of lower density and increases the chances of inbreeding.

This paper deals primarily with the effect on mental disorder of the cultural factors related to popula-

tion density. The aim is not to depreciate biologic factors, but to simplify the explanation of the findings and to discover how extensively cultural explanations are applicable. To do this the following hypothesis has been adopted: mental disorders in any community are to a great extent determined, both in type and in prevalence, by the culture of the community. The amount and types of mental stress and the acceptability of both normal and abnormal outlets from stress are parts of the culture and determine the type of disorder manifested.

The hypothesis presented by Faris and Dunham¹⁰ that communication is essential for normal mental development and that social isolation makes for mental breakdown appears to be especially pertinent to these findings.

RESULTS

In Table 1 the rates for all major causes of psychiatric rejection are related to different population densities. The rates for all communities with a population density of over 500 per square mile show a steplike increase in mental disorders from 7.5 up to 14.0 per cent with increased population

TABLE 1. *Relation of Percentage Rejected for All Major Psychiatric Causes to Community Density of Population.*

DENSITY PER SQUARE MILE	No. EXAMINED	REJECTION RATE	SOCIOECONOMIC LEVEL
		%	
Less than 500	2,856	12.1	D+
501-999	4,478	7.5	B-
1000-1999	6,340	8.5	C+
2000-4999	8,056	9.2	C
5000-9999	13,322	9.5	C
10,000-19,999	14,108	10.6	D
20,000 or over	10,840	14.0	E

density. The communities of less than 500 people per square mile stand out markedly from this pattern with the high rate of 12.1 per cent. This table indicates that to a considerable extent the relation to density of the total rate of psychiatric rejection can be explained on the basis of variation in socioeconomic levels. Only in the consideration of those communities that present rates for mental disorder varying from that to be expected on the basis of socioeconomic level, and in that of specific mental disorders, is the importance of population density alone demonstrated. Each of the communities of density of less than 500 per square mile was investigated, and some presented an unexpected deviation from the average rate for that density level. The three communities that had especially high rates included isolated areas and appeared to represent the features of degenerate rural communities in which the ill effects of isolation and of inbreeding may exist.

A study was made of the communities that had the highest rates of mental disorders and those that

the lowest. Of the 13 communities with extremely high rates, 8 were in the extreme density bracket (over 20,000 people per square mile). By contrast, of the 13 communities with extremely low rates, not one was in either extreme density bracket (under 500 or over 20,000 population density). Ten of the 13 were in areas characterized by one-family or two-family houses and 9 were in suburbs of Boston.

In order to define the interrelation of socioeconomic status and population density, the socioeconomic level was determined of those communities in each density level that varied in rate of mental disorders from the average rate of the group as a whole. Twelve of the 14 communities with low rates for mental disorders were of a higher socioeconomic level than that of the density group to which they belonged, confirming the influence of socioeconomic level within the same population density. A similar study was made of differences in population density of communities in each socioeconomic level whose rates varied from the group average. Those communities with populations of less than 500 and over 20,000 per square mile tended to have higher rates than the group average.

Although the total psychiatric rejection rate does not reveal the extent to which differences in rate can be directly attributed to density of population, it is apparent when the separate causes of rejection are examined that change in type of disorder rather than in amount of disorder is notable in different density levels.

Mental Deficiency

The relation of mental deficiency to population density is represented in Table 2. An outstanding finding is that throughout the entire intermediate range of density from 500 up to 20,000 per square mile there was no significant difference in the rate of mental deficiency. The highest rate was found in

TABLE 2. *Relation of Percentage Rejected for Mental Deficiency to Community Density of Population.*

DENSITY PER SQUARE MILE	REJECTION RATE
	%
Less than 500	2.7
500-999	1.3
1000-1999	1.5
2000-4999	1.6
5000-9999	1.3
10,000-19,999	1.2
20,000 or over	2.2

in communities of population density less than 500 per square mile, and the next highest in those of population density at the other extreme, over 20,000 per square mile. The highest rate of mental deficiency in the rural areas confirms the findings of the studies of the draftees of World War I⁸ and that of Dayton.⁵

It is interesting to compare those communities having the highest rates of mental deficiency with

those having the lowest. All but 3 of the 11 communities with high rates of mental deficiency have predominant foreign elements, usually Italian and Portuguese. The relation of mental deficiency to nationality is significant and will be considered in a following paper.¹¹ The 3 other communities with high rates were rural communities having a predominantly Old American population. Each of these communities is known to contain areas of degeneracy and inbreeding. In one there is a neighborhood of albinos. Another includes islands wherein there are large numbers of deaf-mutes whose defects resulted from inbreeding, a fact described by Rosenau.¹² A third has many isolated areas. All these communities have a minority Portuguese population who live in their own settlements among the Old Americans. The high rate among the Portuguese for failure to meet the usual standards is one reason for the high rates found in these communities.

The degree of isolation of the 3 rural communities was further studied by examination of town reports to see to what extent townspeople married outside their community. It was found that they married within their neighborhood to a far greater extent than in other areas.

None of those communities with extremely low rates for mental deficiency were semirural (under 500 people per square mile), and none were dense urban communities (over 20,000 per square mile). The only communities with density over 10,000 per square mile were composed largely of Irish and Jews, who have a low rate for mental deficiency. The communities are all in Boston or suburban or adjacent to it.

Determination of the differences in mental deficiency in communities of different density but of the same socioeconomic level revealed a trend toward decreased rates of mental deficiency with increase of population density.

For an explanation one can first consider that suggested by Dayton⁵; namely, mental defectives tend to drift to the areas of lesser competition that are the least dense areas. To this could be added that the mental defectives originating in the rural areas are likelier to remain there and not to escape to the city, and that inbreeding occurs sufficiently often in certain isolated neighborhoods of these rural communities so that mental deficiency may be increased genetically. It is also likely that the decrease in mental stimuli in the simple rural cultures tends to increase the rates for failure to meet mental tests. Selectees having a rural background are apparently less frequently confronted with situations requiring the concentration and speed needed in an adequate test performance. As a result, they adapt themselves to the test situation less readily than do the urban selectees.

Gillette¹ states that illiteracy is four times as high in rural areas as in urban areas. It is known not

only that urban educational facilities are better, but also that the urban child's school attendance receives more social encouragement and statutory enforcement than does the rural child's. Although our tests are supposed to minimize the influence of education and literacy, it cannot be expected that this aim has been achieved in every case. People who have attended school are able to adjust themselves more quickly than others to the test situation.

Although the relation of mental deficiency to population density is concealed in part by its relation to both socioeconomic level and nationality, it may be concluded that in isolated rural communities there is an increase in the rate of mental deficiency, and that in urban communities, except in the slum areas of foreign population, there is generally a decrease.

Psychopathic Personality

The relation of psychopathic disorders to population density is represented in Table 3. The rate for psychopathic personality is high in rural communities, but the highest rate is in the densest communities. The relation of psychopathic personality to population density is less consistent than it is to socioeconomic level. The findings are notable, however, since previous studies of rates of delinquency, the disorder that compares most closely with our classification of psychopathic personality, have not

TABLE 3. *Relation of Percentage Rejected for Psychopathic Personality to Community Density of Population.*

DENSITY PER SQUARE MILE	REJECTION RATE
	%
Less than 500	3.5
500-999	2.2
1000-1999	3.2
2000-4999	2.8
5000-9999	3.4
10,000-19,999	3.5
20,000 or over	5.7

shown a high rural rate. In view of the fact that the country youth with criminal inclinations tends to migrate to the city to find richer fields for his crimes and a more adventurous existence, it is interesting that there is still a high rate of psychopathic personality in the rural areas.

Two of the low-density communities that had high rates for psychopathic personality also had unusually high rates for mental deficiency and were known to include degenerate areas. One other community with a high rate for psychopathy was of higher population density (1000-1999), but also included at least one community of degenerate Old Americans.

Conflicting factors enter into the rural rates for psychiatric disorders, for in the rural areas both work and play tend to be on a physical level, a circumstance that tends to increase physical outlets for asocial tendencies. On the other hand, asocial

conduct tends to be minimized by the strong social pressure of the family and neighborhood group that is so strong in the rural areas.

Since America has become urbanized with the coming of the industrial era, some rural disorganization has occurred, especially in the last three decades. The wage scale of rural life, even though it allows for security, does not always furnish the physical possessions — for instance, automobiles and movies, which have come to be part of American life. The home and group recreations of the rural community have given way to the commercialized recreations available in the neighboring cities. No longer is the rural youth content with simple rural pleasures. Since his desire for things is stimulated beyond his ability to satisfy it, he comes under the same social stress as does the boy in the slums. The ensuing disorganization is a result of a combination of economic and rural factors.

The extreme density of the urban slums is no doubt associated with their economic level in producing the high rate of psychopathic disorders. The sequence of circumstances may be that poverty tends to keep people in overcrowded slums, and that the overcrowding in turn throws them into too close contact with an abnormally large and diverse group of people. This increases the likelihood of gang development, of personal conflict and of association with older and more criminal associates.

Of those communities with the low rates for psychopathic personality none are of density over 10,000 per square mile and none are in Boston. It may be found with further study that the psychopathic personality of the city is not the same as that of the rural community. Possibly the urban type of psychopath is essentially an aggressive, acquisitive, asocial personality, whereas the rural psychopath is an irresponsible, futile and generally inadequate one.

Chronic Alcoholism

Table 4, showing the relation of chronic alcoholism to population density, reveals a totally different pattern than that of the previously considered mental disorders, for in the case of chronic alcoholism the rate in the rural communities (density less than 500) is not increased. There is a low rate in the 2 community groups of lowest density, and an increase with increasing population density. There appears to be a better correlation of chronic alcoholism with density than with socioeconomic level, for in the study of the latter it was shown that there was no appreciable difference in rates for chronic alcoholism between the communities in the upper segments of desirability (A, B and C communities).⁴

The strong relation of alcoholism to population density is further substantiated by an increase in alcoholism with the increasing density when a correction is made for economic level, and by the fact

that there are no low-density communities (density less than 2000 per square mile) that have a high rate of alcoholism, even though several have a low socioeconomic level.

The stimuli that help to promote drinking tend to increase in direct proportion to the density of the

TABLE 4. *Relation of Percentage Rejected for Chronic Alcoholism to Community Density of Population.*

DENSITY PER SQUARE MILE	REJECTION RATE %
Less than 500	0.6
500-999	0.6
1000-1999	0.8
2000-4999	1.1
5000-9999	1.2
10,000-19,999	1.4
20,000 or over	2.1

population. The farmer is not constantly confronted by whisky and wine advertisements and by bars and cafés. Not only stimuli but also opportunities are more frequently increased with density. Granted that the confirmed alcoholic addict will go far for a drink, somewhere in his development the matter of opportunity for frequent drinking must be important. The man who must pass a bar on every corner as he returns from work would be expected to drink oftener and more than if he had to go several miles to the nearest village to get a drink. Furthermore, the long working hours of the farmer and the time spent at sea by the fisherman decrease the frequency of their drinking.

The closer family life of the rural and semirural communities is conducive to more drinking at home and less in taverns and bars. To what extent this factor affects the incidence of alcoholism is not known, but it is quite possible that the man who drinks at home is favorably influenced by his wife and family to drink moderately, in contrast to the man in the tavern or at the bar, who is so often encouraged by his friends to drink to excess.

A further factor is that of the relation of drinking to sociability. In the rural areas, because of the lack of and need for gregarious living, there is a higher degree of sociability within the neighborhood whenever it is possible for people to get together. Because of the great congestion of the city, barriers are drawn up that isolate the individual from the crowd. In the urban settings the restraints of privacy that have become customs retard sociability, and alcohol serves to dissolve a man's restraint and to aid that freedom of social intercourse that occurs in the rural setting without its aid.

To emphasize density is not to minimize the other factors affecting alcoholism. There is an acknowledged gravitation of the alcoholic addict into a poorer community; there are nationalities with religious or ethical taboos against alcoholism, and there are others with excessive rates for alcoholism, a factor that will be shown in a following paper.¹¹

The question of acceptability of drinking is much disputed, and varies as much with local culture as does any other habit or custom, but in this consideration we point out only the importance of the relation to population density.

PSYCHONEUROSIS

Table 5, showing the relation of psychoneurosis to population density, reveals no consistent pattern. It is notable that the highest rate (4.9 per cent) occurs in the rural communities, with another peak of 4.2 per cent in the communities of 10,000-19,999 population per square mile.

In the relation of psychoneurosis to socioeconomic level, there are a decrease at the extremes and slightly higher rates throughout the communities of intermediate desirability. The finding of high rates in the rural communities is not in agreement with Dayton's⁵ finding of a higher rate of psychoneurosis in hospital admissions from urban communities. This appears to demonstrate the difference in find-

TABLE 5. *Relation of Percentage Rejected for Psychoneurosis to Community Density of Population.*

DENSITY PER SQUARE MILE	REJECTION RATE %

2000-4999	3.5
5000-9999	5.2
10,000-19,999	4.2
20,000 or over	5.7

ings between a cross-section study such as this one and a study involving the selective factors of hospitalization.

The finding of Sherman and Henry¹³ in *Hollow Folk* that the frequency of neuroses increased as the inhabitants moved from Colvin Hollow (an isolated backward community) to the outside world is not substantiated. It may be that the rural communities studied here present features of cultural disorganization and industrialization that are not present in the relatively backward and isolated Colvin Hollow.

A further factor that is probably important is the association of psychoneuroses with fear, ignorance and superstition that often occur in the isolated community. Medical attention, even when available, is in many neighborhoods infrequently sought, and when a man is in pain, he often listens to relatives and friends tell him what his trouble is or how they have seen someone die with just such a pain. Instead of going to a physician to obtain the reassurance of a diagnosis, he permits his fears to become so multiplied and aggravated that the apprehension and anxiety continue long after the pain is gone. Although competitive stress is not great in isolated rural areas, boredom often makes illness the most dramatic and interesting thing in

only that urban educational facilities are better, but also that the urban child's school attendance receives more social encouragement and statutory enforcement than does the rural child's. Although our tests are supposed to minimize the influence of education and literacy, it cannot be expected that this aim has been achieved in every case. People who have attended school are able to adjust themselves more quickly than others to the test situation.

Although the relation of mental deficiency to population density is concealed in part by its relation to both socioeconomic level and nationality, it may be concluded that in isolated rural communities there is an increase in the rate of mental deficiency, and that in urban communities, except in the slum areas of foreign population, there is generally a decrease.

Psychopathic Personality

The relation of psychopathic disorders to population density is represented in Table 3. The rate for psychopathic personality is high in rural communities, but the highest rate is in the densest communities. The relation of psychopathic personality to population density is less consistent than it is to socioeconomic level. The findings are notable, however, since previous studies of rates of delinquency, the disorder that compares most closely with our classification of psychopathic personality, have not

TABLE 3. *Relation of Percentage Rejected for Psychopathic Personality to Community Density of Population.*

shown a high rural rate. In view of the fact that the country youth with criminal inclinations tends to migrate to the city to find richer fields for his crimes and a more adventurous existence, it is interesting that there is still a high rate of psychopathic personality in the rural areas.

Two of the low-density communities that had high rates for psychopathic personality also had unusually high rates for mental deficiency and were known to include degenerate areas. One other community with a high rate for psychopathy was of higher population density (1000-1999), but also included at least one community of degenerate Old Americans.

Conflicting factors enter into the rural rates for psychiatric disorders, for in the rural areas both work and play tend to be on a physical level, a circumstance that tends to increase physical outlets for asocial tendencies. On the other hand, asocial

conduct tends to be minimized by the strong social pressure of the family and neighborhood group that is so strong in the rural areas.

Since America has become urbanized with the coming of the industrial era, some rural disorganization has occurred, especially in the last three decades. The wage scale of rural life, even though it allows for security, does not always furnish the physical possessions — for instance, automobiles and movies, which have come to be part of American life. The home and group recreations of the rural community have given way to the commercialized recreations available in the neighboring cities. No longer is the rural youth content with simple rural pleasures. Since his desire for things is stimulated beyond his ability to satisfy it, he comes under the same social stress as does the boy in the slums. The ensuing disorganization is a result of a combination of economic and rural factors.

The extreme density of the urban slums is no doubt associated with their economic level in producing the high rate of psychopathic disorders. The sequence of circumstances may be that poverty tends to keep people in overcrowded slums, and that the overcrowding in turn throws them into too close contact with an abnormally large and diverse group of people. This increases the likelihood of gang development, of personal conflict and of association with older and more criminal associates.

Of those communities with the low rates for psychopathic personality none are of density over 10,000 per square mile and none are in Boston. It may be found with further study that the psychopathic personality of the city is not the same as that of the rural community. Possibly the urban type of psychopath is essentially an aggressive, acquisitive, asocial personality, whereas the rural psychopath is one an irresponsible, futile and generally inadequate one.

Chronic Alcoholism

Table 4, showing the relation of chronic alcoholism to population density, reveals a totally different pattern than that of the previously considered mental disorders, for in the case of chronic alcoholism the rate in the rural communities (density less than 500) is not increased. There is a low rate in the 2 community groups of lowest density, and an increase with increasing population density. There appears to be a better correlation of chronic alcoholism with density than with socioeconomic level, for in the study of the latter it was shown that there was no appreciable difference in rates for chronic alcoholism between the communities in the upper segments of desirability (A, B and C communities).⁴

The strong relation of alcoholism to population density is further substantiated by an increase in alcoholism with the increasing density when a correction is made for economic level, and by the fact

Rural communities are for the most part characterized by isolation, monotony of existence and lack of those commercialized recreations — theaters, soda fountains, bars and night clubs — that have come to be so demanded by urban society — and by lack of those business opportunities that modern civilization requires. Wages are adequate to buy those things considered necessary in rural culture — simple food, simple clothing and shelter — but not those things considered necessary in modern culture. Radios, automobiles, washing machines, flush toilets, vacuum cleaners and electric lights are difficult to obtain with rural wages. On the other hand, in the large cities, represented here by Boston, where the recreational facilities, business opportunities and modern conveniences that the rural areas lack are found, there are also the undesirable features of congestion and overcrowding, with the resultant lack of privacy, fresh air, open fields and woods. Commercialized recreation takes such a dominant place in urban life that home life is often weakened. The intensity of economic and social competition that overstimulates the individual may blunt his ethical sensitivity and make economic success his only important goal. The hopelessness of failure or the fear of it in such competition is as abject as the morbid discontent, apathy or boredom engendered in the rural areas.

Faris and Dunham¹⁰ find the factor of social isolation to be important in mental disorders in the densest urban rooming-house areas. Perhaps the anonymity afforded in the rooming-house area of the great city offers as great a degree of social isolation as do the rural areas, and perhaps the increased isolation in both these extremes of population density is responsible for the increase of rates of mental disorders at the extremes.

Only between these two extremes is there present the mean that satisfies most fully the aspirations of modern life. In the small city, and to a lesser extent in the moderate-sized city, there are those advantages of interest, stimulation, excitement of easily accessible recreational facilities, business opportunities and modern conveniences that are lacking in the rural communities, without the loss of the rural advantages of open fields, woods and strong family life. Security still exists to a great extent. The competition is not so intense as in the great city, aspirations are not so high, and the opportunities that are present are not overwhelming or confusing. The personality is not crushed by intense overcrowding and competition, nor is it stimulated to intensely aggressive action, as in the great city, nor stifled by isolation and boredom, as in the rural areas.

It is not surprising to find both the rural areas and the great city having similar rates for mental disorders, for both types of communities have many

unfavorable features. The most adequate people, as judged by their adaptation to modern life, migrate to the urban communities from both the rural and dense urban areas, leaving the less able people behind. Thus, the increased numbers of inadequate people left at the undesirable extremes of density, as well as unfavorable factors of these types of communities, account for the high psychiatric rates at the two extremes.

SUMMARY

The rejection rates for the major mental disorders found in selectees examined at the Boston Armed Forces Induction Station are compared with the population densities of the communities from which the selectees came, with the following findings.

Mental disorders differ in type in areas of different population density, irrespective of factors of socioeconomic level and national origin.

The highest rate of disorders are at the two extremes, with the highest rate of mental deficiency and psychoneurosis in the semirural areas and the lowest in the small cities.

The highest rate of chronic alcoholism and of psychopathic personality is in a large city (Boston); the lowest rate for chronic alcoholism in the semirural communities, and the lowest for psychopathic personalities in the small cities.

Only chronic alcoholism is correlated with population density throughout its complete range. It appears more closely associated with density than with socioeconomic level.

This study points to the need of intensive study in communities of different population density regarding the influence of the community environment on mental health.

life. Births, deaths, accidents and operations are events of great social importance to the community, and as a result, neurotic manifestations are encouraged, especially among those who have few other ways of gaining attention.

COMMUNITIES OF A PREDOMINANT NATIONALITY BUT OF MARKEDLY DIFFERENT DENSITIES

Fortunately, the 4 communities that had the highest proportion of people of Italian origin represented an extremely wide range of density. They included at one extreme a mill town with outlying rural areas, and at the other, one of the world's most crowded slums. Their rates for major psychiatric disorders followed roughly the pattern of all communities arranged according to density (Table 6).

moderate-sized cities, and is exceeded only by the rate for a large city (Boston). Their rate for chronic alcoholism is lower than in the urban communities of all sizes.

Towns and small and moderate-sized cities. Cities of a great variety of size present similar patterns of rates for mental disorders. Even the pattern for large towns is similar to that in urban areas, just as the characteristics of towns, presenting as they do urban features on a small scale, bear more resemblance to those of the cities than to those of rural areas.

The rates for mental deficiency and psychopathic personality are comparatively low in the urban communities, increasing gradually with the size of the community, and are highest in the semirural

TABLE 6. *Rejection Rates for Psychiatric Disorders in Four Italian Communities of Markedly Different Population Densities.*

COMMUNITY	POPULATION DENSITY	MENTAL DEFICIENCY RATE	PSYCHOPATHIC PERSONALITY RATE	CHRONIC ALCOHOLISM RATE	PSYCHO-NEUROSIS RATE	PSYCHOSES RATE	TOTAL RATE
		%	%	%	%	%	%
C 51	60,000	5.2	6.9	1.2	4.5	.39	18.1
C 21	20,000	3.8	4.4	1.4	2.9	.60	13.1
C 89	7,000	1.0	1.8	0.8	3.9	.00	7.4
C 201	1,500	2.1	2.4	0.3	5.7	.30	10.8

With the variable factor of nationality thus controlled, the great similarity between the variations in this table and those in Tables 1 to 5 indicates how significant density is in determining both the extent and character of mental disorders, and how imperative it is, in studies of nationality, to make correction for both socioeconomic level and population density.

SIZE OF COMMUNITIES

In order to present a study of the relation of mental disorders to population density that would conform to other studies based on the size of the community rather than on its density, communities

and very dense communities. The rate for alcoholism increases in proportion to the size of the city, being lowest in semirural communities and highest in a large city (Boston). The rates for psychoneurosis, although lower than that in semirural communities, do not vary significantly in cities of different size.

Large city. In a large city (Boston), there is an extreme density not to be found in the merely urban environment. The rate for mental deficiency is increased consistently with its increase throughout the small cities. The rates for psychopathic personality and chronic alcoholism increase so sharply that the single factor of density seems inadequate

TABLE 7. *Rejection Rates for Psychiatric Disorders in Communities of Different Size.*

SIZE	SOCIOECONOMIC LEVEL	MENTAL DEFICIENCY RATE	PSYCHOPATHIC PERSONALITY RATE	CHRONIC ALCOHOLISM RATE	PSYCHO-NEUROSIS RATE	PSYCHOSES RATE	TOTAL RATE
		%	%	%	%	%	%
Semirural communities	D+	2.4	3.7	.6	4.4	.45	11.6
Towns	B	1.3	2.4	.9	3.3	.09	8.0

Moderate-sized cities ...	C-	1.6	3.2	1.2	3.4	.35	9.8
Large city	D-	1.8	4.8	1.8	3.7	.31	12.4

were arranged on the basis of their sizes (Table 7). This not only furnished a comparable study but also served as a summary of the findings.

Semirural communities. The rates for mental deficiency and psychoneurosis are higher in these areas than in urban communities of all sizes. The rate for psychopathic personality in semirural communities is higher than that in either the small or

to account for the increase. The rate for psychoneurosis is unchanged.

COMMENT

In communities of varying size different patterns of mental diseases are present that are most significant at the two extremes, the largest city and the semirural areas.

The history of onset is practically always an infection superimposed on injured or broken skin — often the result of a slight bruise, abrasion or insect bite. The ulceration appears to be unable to gain a foothold on healthy tissue. These infections are most frequent when the troops are in combat or go out on patrol duty. Although at such times the men are usually fully clothed, they suffer scratches through their clothing. Lowered body resistance and a diet inadequate in vitamins have been suggested as factors in the etiology, but it has not been possible to confirm this theory.

PATHOLOGY

It was impossible to prepare sections for pathological examination. According to Stitt,¹ the histologic characteristics are as follows: the tissue undergoes coagulation necrosis; there is an upper layer of coarsely meshed fibrin containing degenerating polymorphonuclear leukocytes, spirochetes and fusiform bacilli; the epithelium surrounding the ulcer is thickened; its walls and base consist of granulation tissue with a surrounding area of lymphoid and plasma cells and fibrous tissue; lastly, spirochetes are found in the surrounding tissue over an area of 1 or 2 cm. — which may account for the poor results obtained by the use of local applications.

SYMPTOMS

The lesion described above soon develops a dirty-greenish-gray pseudomembrane, which is usually adherent and, on removal, reveals a relatively deep, excavated ulcer. This ulcer may become larger or remain the same size, with the formation and reformation of the membrane. The lesions are usually on the extremities, most frequently on the lower legs. They may be single or multiple, with as many as ten to fifteen on one leg. They vary from 1 to 7 cm. in diameter. The severity ranges from mild to marked, the majority of our cases being moderate. The duration in the acute cases is two or three weeks, and in chronic cases, two to three months — in some cases as long as six to eight months. Approximately 8 per cent of the cases show moderate to marked secondary infection. The ulcers are somewhat sore but not painful. Fever is absent or slight, and no constitutional reactions occur. There is no increase in the white-cell count, and the red-cell count is normal. Kahn tests of the blood serum give a negative reaction.

PROGNOSIS

These ulcers have not been watched long enough for one to observe whether they are self-limited. They probably are not, for the duration in many cases has been months, and even these cases had some treatment. The lesions heal with brown to red scar tissue. Over periods of six to eight months,

similar lesions have not faded appreciably and leave disfigurement, since the ulcer invariably extends into the subcutaneous tissue. Although its old site appears as a weak resisting point for reinfection or ultimate breakdown, this does not seem to be the case, and there have been only 2 cases in which a second lesion was superimposed on an old site.

TREATMENT

The treatment of these ulcers presented a problem. From the start it was apparent that they would not respond adequately to ordinary aseptic care. To

FIGURE 2. Confluence of Two Lesions.
The ulceration measured 3 by 2 cm. Note the irregular margin and the brawny induration about it.

evaluate all the forms of treatment recommended by Stitt¹ and to ascertain which was the most suitable, various medicants and procedures were used in the first half of the cases of this series. The later cases were treated by the method of choice. The more favored methods were used in a large number of test cases, and the less favored in a smaller series. At least a two-week trial was given any treatment before it was given up as having little value. The methods of treatment used were as follows.

Potassium permanganate diluted to 1:5000 and given in the form of hot packs, caused little improvement, nor did a 6 per cent solution painted on the lesions give better results.

Sodium iodide orally and *hydrogen peroxide* locally, as has been recently recommended, were tried, with no favorable results. The procedure was to give 1 gm. of sodium iodide orally three times a day. One to two hours later, when the concentration of the iodide in the blood stream was supposedly greatest, a pack of a 1 to 3 per cent solution of hydrogen peroxide, which had been made acid with acetic acid, was placed on the ulcer. Theoretically, the iodide combines with the hydrogen peroxide, setting free nascent iodine in the tissue, which acts as a bactericide.

Copper sulfate in a 10 per cent aqueous solution or a 30 per cent glycerin solution, applied locally, was ineffective.

TROPICAL ULCER

CAPTAIN MAXWELL H. FEINMAN, M.C., A.U.S.

SAN FRANCISCO

ETIOLOGY

SINCE going into operation in a South Pacific area, the dermatological service has been confronted with a type of skin ulcer that is entirely new to most of the medical officers. With little definite knowledge, and a paucity of written material on this type of skin lesion, the complete armamentarium of medical resourcefulness in this area, or as near complete as possible, has been devoted to the treatment of these patients, the main standby being the sulfonamide drugs. The ulcers eventually heal, but only after long periods of time, many lost or inefficient fighting days and a heavy attendance at sick call.

It must be remembered that for the work here reported laboratory facilities were meager, bacteriologic studies practically nil and pathological examination a scarcely hoped-for dream. Nevertheless, many tropical ulcers have been treated, all available and recommended therapeutic agents, and several that were not recommended have been tried, and definite conclusions have been reached. These are presented, together with a suggested course of treatment, for the benefit of all concerned. It is believed that such a presentation will be a definite advantage to others who have been thrown into a new environment with its own peculiarities.

The only source of detailed information on this subject to be found in the literature is Stitt's¹ *Diagnosis, Prevention and Treatment of Tropical Diseases*. I am greatly indebted to this fine book, from which I shall frequently quote.

This disease is variously known as *ulcus tropicus*, tropical sloughing phagedena and Naga sore. It consists of an acute or chronic skin lesion, of uncertain etiology but closely related to the presence of spirochetes and fusiform bacilli, and characterized by an irregular or rounded appearance, — usually the latter, — indurated edges, an excavated base, a dirty-greenish-gray sloughing membrane and red granulation tissue in the base and walls. The lesion seems to be different from that recently described by Dostrovsky and Sagher² as phagedenic ulcer, which has an undermined edge and no evidence of spirochetes or fusiform bacilli, and is best treated by the local application of sulfapyridine.

According to Stitt¹ this disease is most frequent in Amazonia, and is prevalent in India, Indo-China, southern China and the Philippines. It is said to be the chief cause of disability among laborers in Malaya, and was studied extensively by James³ in the Solomon Islands. The number of cases that find their way into the hospital is in all probability not greater than 50 per cent of the total.

The exact etiologic agent is as yet uncertain, but James³ found spirochetes in 65 to 75 per cent of the ulcers and fusiform bacilli in all. Our findings closely follow these figures. Of an appreciable number of early cases, 70 to 75 per cent showed positive smears for spirochetes. Of the later cases, only 50 per cent were positive for these organisms. Practically all the ulcers contained fusiform bacilli. Another frequent finding, which occurred in 60 per cent of the cases, was the presence of diplococci and diplobacilli that stained blue with Giemsa's stain or Loeffler's methylene blue. Gram's stain was not available, so that it could not be determined whether these organisms were gram-positive or gram-negative. In many cases, diplococci and diplobacilli were the only organisms reported.

The spirochete is a slender, delicate spirillum with a variable number of shallow undulations. It resembles and is possibly identical with *Spirochaeta vincenti*. The fusiform bacilli are plump and 5 to 7 microns in length, with straight or slightly tapered ends; they also stain blue with Giemsa's stain or methylene blue and resemble or are the same as those found in Vincent's angina. Many investigators believe that the spirochetes and bacilli are different

FIGURE 1. Lesion of Three Weeks' Duration (1.2 cm in diameter)
Note the indurated, raised edges

stages of the same organism. Tunnickliff⁴ states that in cultures of fusiform bacilli spirochetes appeared after five days. Smith⁵ states that he, too, has seen spiral forms take the place of fusiform bacilli in pure culture. The present findings show no evidence that a fungus is the etiologic agent.

The history of onset is practically always an infection superimposed on injured or broken skin — often the result of a slight bruise, abrasion or insect bite. The ulceration appears to be unable to gain a foothold on healthy tissue. These infections are most frequent when the troops are in combat or go out on patrol duty. Although at such times the men are usually fully clothed, they suffer scratches through their clothing. Lowered body resistance and a diet inadequate in vitamins have been suggested as factors in the etiology, but it has not been possible to confirm this theory.

PATHOLOGY

It was impossible to prepare sections for pathological examination. According to Stitt,¹ the histologic characteristics are as follows: the tissue undergoes coagulation necrosis; there is an upper layer of coarsely meshed fibrin containing degenerating polymorphonuclear leukocytes, spirochetes and fusiform bacilli; the epithelium surrounding the ulcer is thickened; its walls and base consist of granulation tissue with a surrounding area of lymphoid and plasma cells and fibrous tissue; lastly, spirochetes are found in the surrounding tissue over an area of 1 or 2 cm. — which may account for the poor results obtained by the use of local applications.

SYMPTOMS

The lesion described above soon develops a dirty-greenish-gray pseudomembrane, which is usually adherent and, on removal, reveals a relatively deep, excavated ulcer. This ulcer may become larger or remain the same size, with the formation and reformation of the membrane. The lesions are usually on the extremities, most frequently on the lower legs. They may be single or multiple, with as many as ten to fifteen on one leg. They vary from 1 to 7 cm. in diameter. The severity ranges from mild to marked, the majority of our cases being moderate. The duration in the acute cases is two or three weeks, and in chronic cases, two to three months — in some cases as long as six to eight months. Approximately 8 per cent of the cases show moderate to marked secondary infection. The ulcers are somewhat sore but not painful. Fever is absent or slight, and no constitutional reactions occur. There is no increase in the white-cell count, and the red-cell count is normal. Kahn tests of the blood serum give a negative reaction.

PROGNOSIS

These ulcers have not been watched long enough for one to observe whether they are self-limited. They probably are not, for the duration in many cases has been months, and even these cases had some treatment. The lesions heal with brown to red scar tissue. Over periods of six to eight months,

similar lesions have not faded appreciably and leave disfigurement, since the ulcer invariably extends into the subcutaneous tissue. Although its old site appears as a weak resisting point for reinfection or ultimate breakdown, this does not seem to be the case, and there have been only 2 cases in which a second lesion was superimposed on an old site.

TREATMENT

The treatment of these ulcers presented a problem. From the start it was apparent that they would not respond adequately to ordinary aseptic care. To

FIGURE 2. Confluence of Two Lesions.
The ulceration measured 3 by 2 cm. Note the irregular margin and the brawny induration about it.

evaluate all the forms of treatment recommended by Stitt¹ and to ascertain which was the most suitable, various medicants and procedures were used in the first half of the cases of this series. The later cases were treated by the method of choice. The more favored methods were used in a large number of test cases, and the less favored in a smaller series. At least a two-week trial was given any treatment before it was given up as having little value. The methods of treatment used were as follows.

Potassium permanganate diluted to 1:5000 and given in the form of hot packs, caused little improvement, nor did a 6 per cent solution painted on the lesions give better results.

Sodium iodide orally and *hydrogen peroxide* locally, as has been recently recommended, were tried, with no favorable results. The procedure was to give 1 gm. of sodium iodide orally three times a day. One to two hours later, when the concentration of the iodide in the blood stream was supposedly greatest, a pack of a 1 to 3 per cent solution of hydrogen peroxide, which had been made acid with acetic acid, was placed on the ulcer. Theoretically, the iodide combines with the hydrogen peroxide, setting free nascent iodine in the tissue, which acts as a bactericide.

Copper sulfate in a 10 per cent aqueous solution or a 30 per cent glycerin solution, applied locally, was ineffective.

Formaldehyde in a 7 per cent solution, applied locally, appeared to clean up the ulcer, but the latter showed no evidence of closing over.

Cleansing with *alcohol* and covering the area with an occlusive vaseline dressing, which was left in place for a period of three days, was unsatisfactory.

Human plasma in the dried form or as a four-times concentrated solution, applied locally, seemed to have some value but was eventually given up as inadequate. The dried plasma gave better results than did the solution.

Bismuth subsalicylate in daily local applications gave no favorable results. Intramuscular injections of 0.5 cc. at the start, followed by 1.0 cc. every other day for three doses and then twice a week to a limit of ten injections, showed good results if sulfanilamide powder was used locally at the same time and an occlusive vaseline dressing was applied when the ulcer appeared to be clean. The vaseline dressing was left in place for three days. Although this method often gave excellent results, it did not seem to meet the situation. The ulcers progressed to a nearly healed stage, but from then on many took a long time to heal.

Sulfanilamide or *sulfadiazine* powder used locally seemed to clean the ulcer, but there was no evidence of healing.

Neoarsphenamine, either in a 3 per cent glycerin solution or in powder form, applied locally, had little apparent effect in healing the ulcer.

Ferrous sulfate and *vitamins*. On the basis of a vitamin deficiency and lowered body resistance, the first half of the patients were given 2 gm. of ferrous sulfate daily and tablets providing 15,000 units of vitamin A, 1200 units of vitamin D, 225 mg. of vitamin C (ascorbic acid), 6 mg. of thiamine chloride, 9 mg. of riboflavine and 60 mg. of nicotinamide,

FIGURE 3. Lesion of Six Weeks' Duration (3 by 2 cm.). Note the thickened edges, the granulating base and the excavation.

to which was added 150 mg. of niacin (nicotinic acid), daily. There was no apparent improvement compared with the later cases, in which ferrous sulfate and vitamins were given only when indicated.

Periods of exposure to *sunshine* (ultraviolet rays) seemed to have no special value.

Mild *mercurous chloride ointment* was used locally. This seemed to clean the ulcer, but there was no evidence of healing.

Acridflavine in 1:1000 solution, which has been used by other investigators, and *vaccine therapy*, which has been recommended in spite of relatively unsatisfactory results, were not available. *Penicillin* was not available in quantities to warrant its use.

Mapharsen was substituted for the recommended intravenous neoarsphenamine or novoarsenobenzol. In a 0.3 per cent solution or in powdered form applied locally, it caused moderate improvement but did not close the ulcer. The best results were obtained from intravenous injections. The often seen brawny induration and soreness about the site of the ulcer disappeared after one or two injections, but the greenish-gray membrane continued to form. For this reason sulfanilamide or sulfadiazine powder was also used locally. This form of treatment gave by far the best results. In five to seven days the ulcer became clean, and the induration and soreness rapidly disappeared. In about ten days the ulcer began to appear smaller, with new epithelium growing in from the edges. At the present time, the average ulcer heals and the patient is discharged from the hospital in two or three weeks. Needless to say, aseptic dressings and technic are used. Large ulcers take longer to heal, and early or small ones respond faster than do chronic ones. The dosage used was 0.03 gm. for the first dose and 0.06 gm. for the subsequent doses. The first three doses were given three days apart and the remaining doses five days apart, for as long as indicated. Reactions to the Mapharsen occurred in only 3 cases, and were mild.

Curettage and skin grafting was not necessary in most cases. Two recent cases were curetted, solely for the purpose of removing thick, firm and heavy necrotic tissue. One of these ulcers is filling in rapidly from the bottom, and both are showing healthy granulated tissue. It is possible that these cases will do better with later skin grafting, although in a recent elderly patient a similar ulcer on the lateral aspect of the knee, 6 cm. in diameter but not deep, healed completely and firmly in six weeks, with a scar only 2.5 cm. in diameter.

Ambulatory Treatment

Recently, members of a line battalion have been treated as ambulatory patients with the method of choice, namely, intravenous Mapharsen, local sulfanilamide powder and occlusive dressings. The first patient had numerous lesions on both lower legs of superficial or moderate degree. The duration of the disease was two months, with numerous visits on sick call and little or no evidence of healing. Under treatment, with daily dressings for one week and

When every fifth day, the lesions healed in three weeks. The second case was an indurated lesion on the lower leg of three weeks' duration. This healed completely in three weeks. The third patient had several superficial ulcers on both arms of four

FIGURE 4. Lesion of Four Weeks' Duration (3.8 by 5.0 cm.). This eventually healed, with a flat scar one third size of that shown.

weeks' duration. These dried and healed following one injection of Mapharsen.

CONCLUSIONS

Spirochetes and fusiform bacilli appear to be a definite factor in the production of tropical ulcers.

These ulcers usually occur on broken or injured skin. Therefore, all troops should be cautioned about this, so that they may promptly apply a bactericide and first-aid dressing, in an effort to prevent ulcer formation at these points.

Medical officers should learn to recognize these ulcers early. They should not experiment with the easily available sulfonamide drugs or ointments, gentian violet, or Frazier's solution to see what will happen, but should proceed directly to treat vigorously with intravenous Mapharsen, and apply sulfanilamide or sulfadiazine powder to the ulcers, as their appearance or bacteriology may direct. After the ulcer has become clean, an occlusive vaseline dressing should be applied and changed infrequently.

Mapharsen can and should be made easily available to forward echelons, and treatment should be instituted in the early stages of the ulcer. In this way patients can remain ambulatory, with no loss of man-days of work or fighting and no hospitalization.

I am indebted to T/3 Basil L. Miner and T/5 Edward Puskarz, ward supervisor and wardmaster, respectively, for their interest and co-operation in the treatment and care of these patients and to T/5 Jack C. Renner for his work in smear and slide diagnosis.

THE USE OF BLOOD IN THE TREATMENT OF DUODENAL FISTULA

PETER A. CONSALES, M.D.,* AND WILLIAM T. O'CONNELL, M.D.†

BOSTON

CASE REPORT

EXTERNAL duodenal fistula constitutes a problem of great importance: and if not corrected usually terminates fatally.¹ Fortunately, it is a rare complication. Up to 1923 only 61 cases had been reported.² In a more recent communication by Bartlett and Lowell,³ however, 128 authentic cases were presented in what was believed to be a complete review of the literature from 1865 to 1937. It is apparent that within the last two decades the prevalence of this disease has increased, perhaps owing to the greater number of operative procedures carried out in the right upper quadrant of the abdomen.

The mortality is still extremely high. Most authors consistently report an approximate mortality of 50 per cent irrespective of the procedures used, whether medical or surgical.⁴ Management along conservative measures, however, has considerably reduced the mortality.⁵ According to Kittelson,⁶ 65 cases treated conservatively had a mortality of 23 per cent. Unquestionably the latter treatment has become the procedure of choice within the last ten years, and surgery has been reserved for cases in which there is a definite indication for it.

External duodenal fistula is usually caused by injury to the duodenum during the performance of a surgical operation in the right upper quadrant of the abdomen, such as that on the duodenum itself, the pyloric end of the stomach, the gall bladder, the liver, the hepatic flexure of the colon and the right kidney.⁷ It is not intended to review the etiology in greater detail or to describe the pathologic physiology, the symptoms and the matter of diagnosis of duodenal fistula, inasmuch as these have been adequately dealt with in a recent contribution.³

In this paper is presented a case of external duodenal fistula following an operation for gall-bladder disease in which all known therapeutic methods were tried, with extremely poor results. The effects of dehydration, acidosis and the inevitable extensive and severe excoriation of the skin were so pronounced that a supposedly new method of remedying this trying situation was tried — the use of whole blood in the wound, packing the latter firmly with cotton. Following this procedure the duodenal fistula promptly ceased draining. There was immediate relief in the systemic symptoms, as well as beneficial effect on the surrounding skin, with prompt healing of the fistula.

A. S. (C 55429), a 57-year-old, married woman, was admitted to St. Elizabeth's Hospital on August 8, 1943, with a history of upper abdominal pain and vomiting of 48 hours' duration. The pain was constant, with intermittent exacerbations that had become increasingly severe. For the last few years, the patient had been in good health with the exception of vague digestive disorders, characterized by belching of gas, a bloated feeling and moderate hyperacidity. No similar acute episode had been experienced prior to this one.

On physical examination the patient was obese, weighing 179 pounds, and appeared quite ill, dehydrated and in acute pain, with marked nausea and occasional vomiting. The abdomen was distended and slightly tympanitic. On auscultation no borborygmi were noted. There was marked tenderness, with rebound pains throughout the upper abdomen, and moderate rigidity. No palpable masses were noted. The liver was not palpable. The temperature was 99.8°F., the respirations 25 and the blood pressure 128/80. The red-cell count was 4,610,000 and the white-cell count 10,000, with 76 per cent polymorphonuclear leukocytes. The hemoglobin was 90. The urine was essentially normal save for a slight possible trace of albumin.

Intravenous replacement of fluids was started, and an initial plain film of the abdomen was taken. This showed considerable gas, especially in the upper right quadrant, with mottling over the gall-bladder region that resembled calculi. The patient's general condition did not improve, and the next day a laparotomy was performed through an incision in the upper part of the right rectus muscle. Exploration revealed a small quantity of free bile in the peritoneal cavity. The greater omentum was curled around and adherent to the first and second portions of the duodenum. It was freed by sharp dissection, revealing the first and second portions of the duodenum, which were firmly adherent to the inferior surface of the liver. To expose the gall bladder and its ducts, the adherent duodenum was in turn freed from the liver.

Despite the utmost care in exposing the deeper tissues, which were quite friable, a rent of 2 cm. occurred in the duodenum. This was quickly closed. Two rows of intestinal sutures and a third of linen were used, and the opening was securely covered with omentum. The gall bladder was contracted, cordlike and almost fused into the liver bed; eight stones were extracted. The common duct was of normal size and no stones were palpable. The cystic duct was doubly ligated and divided with a cautery. The contracted, sclerotic gall bladder was so firmly incorporated in the liver tissue that removal was not attempted because of the extent of liver damage inherent in such procedures. Five grams of sulfanilamide was sprinkled in the abdomen. A Penrose drain was inserted in Morrison's pouch and brought out through the lower end of the incision, and the abdomen was closed. The immediate postoperative convalescence was complicated by a bronchopneumonia that cleared up 7 days later with the aid of sulfonamide therapy.

On the 3rd postoperative day, the Penrose drain was withdrawn and only a small amount of bile drainage was noted. On the following day, a greater amount of bile-stained drainage was present and soon increased. The character of the drainage had changed and a marked excoriation of a large abdominal area about the incision had occurred, establishing the diagnosis of duodenal fistula. On the 5th postoperative day, the drainage was profuse and the upper part of the wound had sufficiently separated to permit a clear view of two fistulous openings, the larger one measuring 6 by 2 mm. and the smaller 3 by 2 mm. The skin was protected by equal parts of kaolin and zinc-oxide ointment. Dressings had to be changed every 1 or 2 hours, despite continuous suction

*Assistant surgeon, St. Elizabeth's Hospital.

†Formerly, intern, St. Elizabeth's Hospital.

and an indwelling nasal tube. Donald's⁸ method* was then tried for 3 days, but there was no appreciable relief and the drainage did not diminish. The patient became increasingly weak and was maintained on intravenous therapy. During drainage, particles of undigested food were present and even fruit juices were frequently observed.

Since the methods advocated for this condition had failed, an attempt was made to devise a method that would block the escape of duodenal contents. Packing was considered as holding the possibility of success provided something was used about the packing to prevent leakage. A report on the treatment of leg ulcers with whole blood⁹ gave sufficient impetus to try whole blood and packing empirically. Twenty days postoperatively (15 days after the diagnosis of duodenal fistula had been established), this method was initiated.

The method devised is simple. From 3 to 5 cc. of the patient's blood is procured from an arm vein in a sterile syringe. The abdominal wound is wiped thoroughly dry with gauze, and 2 cc. of blood is sprayed into the bottom of the wound. A wad of cotton is firmly packed against the sinus or sinuses at the bottom of the wound. A little more blood is sprayed around the periphery of the cotton packing. Several layers of cotton may be used, and each time blood is sprayed at the periphery; enough cotton is employed to fill the wound flush with the skin. Two straps of adhesive plaster are applied not too firmly. In this case the wound was so excoriated that no adhesive was used for several days. The outer dressing is changed daily, but the packing is removed every 2 or 3 days.

Following the institution of this method, a marked change was evidenced. During the next 48 hours only serous dampness was noted on the abdominal dressing. The patient's general condition improved, and her appetite and strength likewise increased. On removing the packing it was found to be firmly adherent to the walls of the wound, and healthy granulations were evident. A biopsy specimen from the wall of the fistula was submitted for pathological examination, which was reported as follows:

One corner of the specimen shows stratified squamous-cell epithelium. Underlying and at the margin there is a layer of granulation tissue densely infiltrated with lymphoid cells, polymorphonuclear leukocytes and a few eosinophils. The tissue is moderately vascular. Diagnosis: granulation tissue (Fig. 1).

From then on the wound was repacked every 48 hours. The patient improved steadily and the skin slowly healed. She was out of bed and walking about on September 6, and was discharged on September 12, 34 days postoperatively. At the time of discharge the hitherto gaping abdominal wound was about half its original size and a firm packing was left in situ. From then on convalescence was uninterrupted, with complete healing of the fistula 3 weeks later.

DISCUSSION

Closure of the duodenal defect in duodenal fistula may be accomplished either by operative or by nonoperative measures.¹⁰ Operative procedures have not been encouraging in that surgical intervention is usually carried out at a time when the patient's condition is extremely poor. For such reasons most writers agree that surgery should be reserved for selected cases.¹¹ Furthermore, most

authors are in accord that at present the best hope in dealing with this aggravating complication lies in palliative and conservative measures.¹² A number of methods have thus far been advocated, each

FIGURE 1. Photomicrograph of the Biopsy Specimen. Note the granulation tissue.

with reported successes. The basic principles underlying those generally carried out can be concisely summarized as follows:

Mechanical:

Elimination of positive duodenal pressure by the passage of a tube into the duodenum. This is impossible in the case of a leak from a duodenal stump after gastric resection.

Absorption of the ferments, achieved by the production of an acid medium by continuous irrigation of the wound with a tenth-normal solution of hydrochloric acid, with citric acid, or with 5 per cent solution of tannic acid.

Absorption of the ferments by the application of finely divided charcoal, kaolin or bronzing powder.

Removal of the fluids by continuous suction obtained by a tube inserted in the fistula. (In a modification of this method two tubes are used — one for irrigation of the fistula with peptone water, beef juice and the like, and the other for suction.)

Chemical:

Neutralization of the proteolytic ferments by combining them with an excess of peptone powder, protein, beef juice or similar agents, also whole milk thickened by adding acidophilus bacillus.

Protective:

Protection of the surrounding skin by the application of kaolin and glycerin ointment, boric ointment, liquid latex or the like.

In every method an attempt is made to remove the intestinal digestive contents that constantly

*Donald, not being satisfied with the methods at hand, has described a simple apparatus that he used successfully in a patient who developed a fistula from the duodenal stump twelve days after a subtotal resection of the stomach and a posterior Polya type of anastomosis. The fistula was completely obliterated eight days after the apparatus was applied. Donald's method, in brief, is as follows: A cuff is made from a round standard apertum container, the bottom of which is cut off, the container being firmly applied about the wound and strapped to the skin. A thick ointment composed of 50 per cent glycerin and 50 per cent kaolin is then heavily applied to the inside wall of the container and to the skin adjacent to the fistula. The fluid that drains into the box is aspirated once every hour and subsequently at gradually lengthening intervals, as required. When aspiration is not being carried out, the box is closed tightly by insertion of the lid of the container. The patient is then free to move about in bed as he desires.

pour out of the wound, and whenever possible to collect these juices and feed them back to the patient through an indwelling nasal tube or a jejunostomy. The use of solutions to neutralize chemically the intestinal discharges is in many cases of little value. The application of protective ointments is also of limited value, depending on the character and amount of drainage. Those who have had experience with the persistent drainage from duodenal fistulas realize the many disadvantages inherent in the above methods. Unquestionably the desirable objective is to keep the wound absolutely dry and free from digestive juices if possible, with the hope of aiding the formation of granulation tissues, thus finally obliterating the fistula.

In the present case, this objective was attained by using autogenous blood around the periphery of cotton packing within the fistulous wound. It is realized that the report of a single case is insufficient to warrant any conclusions; yet it seems certain that in this case the rapid growth of granulations obliterating the duodenal defect can be attributed to the use of whole blood.

This appears to be in conformity with the observations of Moorehead and Unger¹³ on the use of residual red cells from different blood groups. They have mixed these and stored them in a refrigerator from a few days to a few weeks, obtaining a gelatinous mass. This they have used as a dressing material for wounds such as open joints, infections, burns and ulcers. The material is reported to aid the ingrowth of new tissues when applied to certain wounds. Seldon¹⁴ has likewise used this gelatinous mass of red cells in postoperative wounds, with encouraging results. In addition, to

eliminate the disadvantage of absorption by the gauze, he has evolved a method of reducing the semiliquid mass of red cells to a fine powder, which is dusted on the wound or applied by a spatula. Seldon's report is encouraging in that the postoperative period is materially reduced.

SUMMARY

Duodenal fistula and its treatment is briefly discussed, and a case is presented.

The treatment of this case by whole blood, topically applied, is described, and the result obtained is discussed.

It is hoped that this method may be applied by others in this trying and serious condition.

MEDICAL PROGRESS

PARENTERAL-FLUID THERAPY*

I. Estimation and Provision of Daily Maintenance Requirements

ALLAN M. BUTLER, M.D.,† AND NATHAN B. TALBOT, M.D.‡

BOSTON

THE last fifty years have witnessed a steady increase in knowledge concerning the metabolic disturbances resulting from starvation and dehydration. In addition, the increased availability of a variety of parenteral solutions and specific nutrients has increased not only the possible effectiveness of parenteral nutrition and repair therapy but also the physician's responsibility in the administration of parenteral fluids. The purpose of this review is to present in outline form such basic data as may be helpful in effectively utilizing his knowledge in the provision of the parenteral therapy that is at hand today or may become available tomorrow. The first part deals with the

rate and his relatively greater load of catabolites presenting for urinary excretion. These large volumes may also be due to a somewhat limited concentrating ability of the kidneys.^{3,4} The urine volumes given in the table appear adequate to provide the volumes required to excrete the increased total osmimoles⁵ that may present for renal excretion incident to operation, traumatic shock, fever, starvation or the debility of illness.⁶⁻¹³ Patients with a renal impairment that limits concentrating ability may have an obligatory renal water loss that is 100 per cent greater than those given in the table.¹⁴ Moreover, insensible water losses as much as 100 per cent above those recorded

estimation and parenteral provision of the daily maintenance requirements of patients who cannot be nourished enterally. The second part will cover the estimation of losses incident to dehydration and the provision of parenteral repair therapy.

ESTIMATION OF DAILY MAINTENANCE REQUIREMENTS

A consideration of maintenance requirements is an obvious prerequisite to logical parenteral maintenance therapy.

Table 1 presents the approximate daily water losses of normal infants, children and older persons who are not performing work or sweating. It should be noted that the infant has a greater water loss per kilogram of body weight than does the adult. His greater insensible loss^{1,2} is associated with his relatively larger surface area and higher metabolic rate; and his greater urine volume per kilogram reflects the infant's higher metabolic

rate and his relatively greater load of catabolites presenting for urinary excretion. These large volumes may also be due to a somewhat limited concentrating ability of the kidneys.^{3,4} As such abnormal losses are not unusual for patients requiring parenteral therapy, their occurrence demands appropriate extra allowances of water above those listed in Table 1. Extreme extrarenal water losses (2000 to 5000 cc.) may be suffered by patients subject to high environmental temperatures.^{1,19-22}

The data of Tables 2 and 3 approximate the normal daily allowances of sodium chloride and

TABLE 2. *Approximate Normal Sodium Chloride Maintenance Allowances Per Day for Resting Nonsweating Persons of Varying Size.*

the fact that such daily sodium chloride needs of infants and adults are satisfied respectively by approximately 125 and 700 cc. of physiologic saline solution. The therapeutic implication of these small maintenance needs of saline solution has been emphasized.^{15-17,23-26} Should all the infant's or adult's parenteral fluid contain 0.85 per cent of sodium chloride, each would obtain approximately 6 or 22 gm. respectively of the salt per day. Such an excess of parenteral solution often results in fluid retention and in a urine volume that is extremely small relative to the fluid intake.^{15-17,26} This normal

in both the renal and extrarenal loss of water.^{1,11} Excessive intravenous dextrose should, however, be avoided because of the possibility of overburdening the liver³⁴ and of inducing an undue hyperglycemia, glycosuria and polyuria. Again, as mentioned in considering Table 1, the allowances of Table 2 and the requirements of Table 3 do not include the repair of losses incident to shock, trauma or illness.

The provision of the protein allowances specified in Table 3 can be accomplished by whole blood or plasma transfusions and the infusion of solutions

TABLE 3. *Approximate Daily Caloric Requirements of Normal Resting Persons of Varying Size, Together with the Daily Dextrose and Amino Acid Allowances* That Theoretically Might Satisfy Them.*

*Available evidence suggests 6 gm. of nitrogen or 40 gm. of amino acid as a reasonable daily allowance for the adult; that for estimating the daily allowances for young resting patients on a high carbohydrate diet is meager.

response is not infrequently falsely interpreted as an indication for more fluid or of circulatory failure or renal insufficiency. In patients receiving a sulfonamide, such an oliguric response to excessive saline solution may be attributed to a deleterious effect of the drug on the kidneys and may result in the discontinuance of a highly desirable therapy. If, on the other hand, the drug is continued, the low urine volume may actually result in an avoidable sulfonamide hematuria—avoidable because the infusion of the same volume of proper parenteral fluids would have provided a urine volume sufficient to allay such a complication.

Whereas the provision of water and sodium chloride allowances is readily accomplished parenterally, the parenteral administration of the normal caloric and protein allowances present more difficulty.

Because in the past dextrose has been more readily available than amino acids, protein or fat for parenterally satisfying caloric requirements, it has usually been used as the source of the major portion of the calories supplied by this route. In so far as parenteral dextrose has satisfied the caloric needs, it has reduced body tissue and nitrogen loss and accomplished a body-protein sparing effect. Today, however, at least the basic protein needs can be readily met by such amounts of parenterally administered amino acids as specified in Table 3.^{8,27-33} The allowances of dextrose given in the table are those required to approximate the basic caloric requirements and thus theoretically effect minimal nitrogen or amino acid requirements. The reduction of protein metabolism to such minimal levels should limit the specific dynamic action of protein and the metabolic rate and provide an economy

of amino acids. In the presence of a significant anemia, whole-blood transfusions are specifically indicated. Plasma transfusions should be employed in the presence of a reduced plasma volume and increased red-cell count, hematocrit or hemoglobin concentration. Although mixtures of the pure amino acids that provide the ten essential to man, together with glycine, have been shown to be effective in maintaining nitrogen balance^{35,36} and to be nontoxic even when injected rapidly,^{36,37} such mixtures are not as yet available for general use. A commercially available enzymatic hydrolysate of casein and pancreatic tissue providing approximately 80 per cent of the total nitrogen as amino acids and 20 per cent as dipeptide* has been shown to be effective in the parenteral provision of basic nitrogen allowance^{8,27-31,33} and superior to such acid hydrolysates as are available for general use today.³⁷⁻³⁹ The enzymatic hydrolysate, however, has definite limitations. If it is infused at more than a moderate rate, nausea, vomiting, hyperpyrexia, polyuria and thrombosis of the vein and edema of the extremity receiving the infusion may occur.^{8,28-31,33,40} Such reactions and the fact that urinary nitrogen may be double that which pertains with the infusion of equivalent amounts of plasma⁴¹ suggest that this preparation might be improved. For the present, reasonable prerequisites to the parenteral administration of amino acids appear to be as follows.

The patient must be unable to ingest sufficient food enterally to meet his caloric and protein requirements.

*The amino acid product known as Amigen (Mead, Johnson and Company).

His basic caloric requirements as specified in Table 3, must be covered sufficiently by par-enteral dextrose,³⁷ with or without fat, properly emulsified for intravenous administration⁴²⁻⁴⁶ to accomplish effective sparing of endogenous nitrogen.

The amino acids should be added to the par-enteral dextrose solutions so that their concentration in the infusion does not appreciably exceed 3.5 per cent and so that the reaction of the solution is approximately pH 6.5.^{8,33} The volume and dextrose content of the infusion will then prescribe a rate that will limit such reactions as listed above.

The total amount of amino acid thus administered should depend on the estimated nitrogen loss sustained by the patient, whose endogenous nitrogen metabolism is being kept minimal by the intravenous infusion of such dextrose and possibly fat as can be effectively utilized. Under such conditions the average daily nitrogen loss in the adult may approximate 6 gm. but may vary from 4 to 20 gm.^{6-11,39} Therefore, approximately 40 gm. of amino acids ($40 \div 6.25 = 6.4$ gm. of nitrogen) will be required per day to cover the average nitrogen loss. In exceptional circumstances double the above requirements of amino acids may be included in the dextrose infusion.

Figure 1 shows the quantities of intravenously administered physiologic saline solution, 5 per

3. It is seen that, if the caloric requirements are to be provided, all the fluid must contain 10 per cent dextrose unless the water intake is to be excessive or unless fat or more amino acids are included in the infusion.

Figure 2 depicts the amounts of such intravenous fluids that will cover the daily requirements of

FIGURE 2.

FIGURE 1.

patients who are heavier than those included in Figure 1. The dextrose concentration has been increased to 15 per cent, since provision of the dextrose allowance (Table 3) by a 10 per cent solution would require the infusion of excessive fluid unless the patient is so dehydrated as to need many cubic centimeters of extracellular fluid or unless fat or more amino acids are included in the infusion.

Because thiamine deficiency may occur within a period of two weeks^{47,48} and because the thiamine requirements may be proportional to the carbohydrate intake,⁴⁹ it seems reasonable to add from 2 to 5 mg. of thiamine per day — depending on the size of the patient — to the glucose infusions. Although there is evidence³⁹ that vitamin deficiencies other than that of thiamine do not develop within several weeks, pre-existing nutritional deficiency or infection may suggest the advisability of providing 0.5 to 0.3 mg. of riboflavin, 5 to 30 mg. of niacinamide and 30 to 100 mg. of ascorbic acid per day. Since these vitamins are unstable in alkaline solution, they should not be added to alkaline solutions.

To support and supplement such maintenance therapy, whole-blood or plasma transfusions should be given as specifically indicated by anemia or by a low concentration of serum proteins.⁵⁰⁻⁵² If par-enteral therapy is required for more than four or

cent amino acids and 10 per cent dextrose that will cover the daily water, salt, caloric and protein requirements of infants as given in Tables 1, 2 and

five days, the desirability of a transfusion of 10 cc. of whole blood or 15 cc. of plasma per kilogram of body weight should be considered. Unless the hemoglobin concentration of the blood is above normal, whole-blood transfusions appear to sustain blood and plasma volumes better than do plasma transfusions.⁵³⁻⁵⁵

Finally, even though such parenteral therapy includes amino acids and vitamins as specified above, it is nutritionally inadequate as regards many intracellular needs, so that the desirability of starting, as soon as possible, oral feedings that supply these intracellular needs should be constantly kept in mind.⁵² Fat-free beef broth and small amounts of milk diluted with an equal volume of water or with some such fluid as ginger ale provide appropriate initial oral nourishment.

MANNER AND RATE OF PARENTERAL ADMINISTRATION

If such are the types and amounts of parenteral fluids required to support the daily maintenance requirements, how should they be administered? Since only solutions given intravenously should contain more than 2.5 per cent dextrose, provision of sufficient dextrose by clysis to provide the basic calories is impracticable. The limitations of so-called "sets" of short infusions and clyses as compared to continuous-drip infusions are illustrated for the infant in Figure 3 and for the adult in Figure 4.

It is readily seen in Figure 3, column A, that a continuous infusion such as that outlined for the 5-kg. infant in Figure 1 closely approximates 100 per cent of the daily water, sodium chloride, caloric and protein requirements. On the other hand, as shown in column B, two short infusions of 20 cc. per kilogram of 10 per cent dextrose in distilled water and two clyses of 30 cc. per kilogram of 0.85 per cent saline solution provide only 85 per cent of the water and 30 per cent of the caloric requirements while overdosing the infant with 260 per cent of the sodium chloride requirement. The substitution of 2.5 per cent dextrose in 0.45 per cent sodium chloride solution as given in column C, for the saline clyses of column B reduces the excessive sodium chloride to 130 per cent of the requirement but still provides only 40 per cent of the daily caloric and 85 per cent of the daily water requirements. Thus, for infants, intravenous infusion is the route of choice in the parenteral provision of the daily requirement of those for whom enteral nutrition is contraindicated. The infusions are usually given most successfully into a scalp vein, the head being immobilized by sandbags and the arms and body by blankets or restraints.⁵⁶

In Figure 4, column E, it is seen that three clyses of 0.85 per cent saline solution, 12 cc. per kilogram, which provide an appropriate water intake, exceed the sodium chloride requirement by 320 per cent and provide no calories whatever.

If the clyses contain 2.5 per cent dextrose in per cent sodium chloride solution (column F), sodium chloride still exceeds the requirement

FIGURE 3.

160 per cent, whereas the calories have been increased to only 14 per cent of the daily requirement. Therefore, the provision of more calories requires the intravenous infusion of some glucose. Since a continuous drip, such as given in column A, satisfies the requirements of water, sodium chloride, calories and amino acids, resort to clyses together with small infusions in the provision of maintenance needs to adults should be avoided if possible.

What, then, is the rate at which these infusion should be administered? It has been suggested that only 10 to 12 gm. of dextrose can be oxidized per hour by an adult and that this rate prescribe a limit to the desirable rate of infusion.⁵⁷ If so only 288 gm. of dextrose should be given a 60-kilo gram adult in twenty-four hours. If this amount of dextrose is given in 2600 cc. of fluid, it means an 11 per cent solution of dextrose administered at the rate of 1.8 cc. or 32 drops a minute for twenty-four hours. Even if the rate of oxidation of dextrose by the infant is assumed to be double that of the adult, the limiting rate for a 5-kilogram

infant would be 2 gm. per hour. In twenty-four hours of continuous infusion only 48 gm. of dextrose could be provided. If this dextrose were provided in the 700 cc. of daily fluid requirement, the concentration of dextrose would be approximately 7 per cent and the rate of infusion 0.5 cc. or 9 drops per minute for twenty-four hours. Thus, for both adults and infants, only approximately 10 per cent of the basic daily calories can be provided by parenteral dextrose if such immediate oxidative capacity is the limiting factor. Infusion rates above these limits appear to be accompanied by an increased storage of glycogen and possibly by such as occurs when similar amounts of carbohydrate are ingested orally. Since most patients receiving parenteral-fluid therapy have suffered some nutritional depletion, the infusion of dextrose at rates that exceed those of its immediate oxidative utilization may be beneficial rather

than out significant hyperglycemia and glycosuria. For the 60-kilogram adult this would mean 48 gm. of dextrose (not 10 to 12 gm.) per hour. Thus, eight hours of infusion would provide 384 gm. and the basic caloric needs of approximately 1500 calories as given in Table 3. Obviously, the continuation of such a rate of dextrose infusion over longer periods of time would provide excess dextrose and calories ($48 \text{ gm.} \times 24 = 1052 \text{ gm.}$ or 4200 calories) and might result in considerable glycosuria.^{23,34, 58, 59}

Acceptance of 0.8 gm. per kilogram per hour as the upper limit of desirable rate of dextrose infusion means that the infusion of such a daily requirement as 70 gm. of dextrose in 700 cc. of fluid to a 5-kilogram infant requires a continuous drip containing 10 per cent dextrose at approximately 0.7 cc. or 13 drops per minute for seventeen hours. For the 60-kilogram adult, the infusion of a daily requirement of approximately 400 gm. of dextrose in 2600 cc. of fluid requires a drip containing approximately 15 per cent dextrose at approximately 5 cc. or 90 drops per minute for nine hours. Since the infusion of 10 to 20 cc. of 5 per cent dextrose per minute for several hours has only a slight accumulative effect on the blood volume⁶¹⁻⁶³ or plasma concentration^{15,16, 26} of the adult, the infusion rates specified above appear rather conservative^{39, 58, 59, 61} unless infection, trauma or cardiovascular function predisposes to pulmonary edema or cardiac failure.^{17, 23-26, 63} Somewhat more rapid rates of infusion over shorter periods, although causing a qualitatively impressive glycosuria, usually result in the urinary excretion of but 2 to 10 per cent of the dextrose injected.^{59, 61} In spite of the fact that such a glycosuria is generally thought to be dehydrating, its diuretic effect may be confined to a very minor increase in urine volume, sodium, chloride and other constituents above that which would usually result from the infusion in the absence of glycosuria.^{17, 26, 59} The factors affecting the not infrequently observed variation in the degree of hyperglycemia and glycosuria resulting from such rates of infusion have not been well defined. Infection, temperature and state of nutrition probably play an important role. Since glycogen has a high potassium content,⁶⁴ the amount of potassium available for combination with dextrose may be a factor in the deposition of glycogen. The amount of phosphorus or cellular enzymes may limit the oxidative utilization as well as the storage of dextrose. Trauma may affect carbohydrate metabolism as much as it does that of nitrogen.^{59, 65, 66} Even though the daily requirements may be given to the adult in nine hours with but little glycosuria, a better utilization of the water and other constituents and greater comfort of the patient might be obtained by administering half the daily requirement by an infusion from 8 a.m. to 12:30 p.m. and the remaining half by an infusion

FIGURE 4.

than harmful if the infusion results in only moderate hyperglycemia and glycosuria without cardiac embarrassment or pulmonary congestion and if the daily amount of dextrose so given does not exceed the daily caloric requirement.³⁴

It has been suggested^{23, 58, 61} that dextrose may be infused for six to twelve hours at a rate of approximately 0.8 gm. per kilogram per hour with-

five days, the desirability of a transfusion of 10 cc. of whole blood or 15 cc. of plasma per kilogram of body weight should be considered. Unless the hemoglobin concentration of the blood is above normal, whole-blood transfusions appear to sustain blood and plasma volumes better than do plasma transfusions.⁵³⁻⁵⁵

Finally, even though such parenteral therapy includes amino acids and vitamins as specified above, it is nutritionally inadequate as regards many intracellular needs, so that the desirability of starting, as soon as possible, oral feedings that supply these intracellular needs should be constantly kept in mind.⁵² Fat-free beef broth and small amounts of milk diluted with an equal volume of water or with some such fluid as ginger ale provide appropriate initial oral nourishment.

MANNER AND RATE OF PARENTERAL ADMINISTRATION

If such are the types and amounts of parenteral fluids required to support the daily maintenance requirements, how should they be administered? Since only solutions given intravenously should contain more than 2.5 per cent dextrose, provision of sufficient dextrose by clysis to provide the basic calories is impracticable. The limitations of so-called "sets" of short infusions and clyses as compared to continuous-drip infusions are illustrated for the infant in Figure 3 and for the adult in Figure 4.

It is readily seen in Figure 3, column A, that a continuous infusion such as that outlined for the 5-kg. infant in Figure 1 closely approximates 100 per cent of the daily water, sodium chloride, caloric and protein requirements. On the other hand, as shown in column B, two short infusions of 20 cc. per kilogram of 10 per cent dextrose in distilled water and two clyses of 30 cc. per kilogram of 0.85 per cent saline solution provide only 85 per cent of the water and 30 per cent of the caloric requirements while overdosing the infant with 260 per cent of the sodium chloride requirement. The substitution of 2.5 per cent dextrose in 0.45 per cent sodium chloride solution as given in column C, for the saline clyses of column B reduces the excessive sodium chloride to 130 per cent of the requirement but still provides only 40 per cent of the daily caloric and 85 per cent of the daily water requirements. Thus, for infants, intravenous infusion is the route of choice in the parenteral provision of the daily requirement of those for whom enteral nutrition is contraindicated. The infusions are usually given most successfully into a scalp vein, the head being immobilized by sandbags and the arms and body by blankets or restraints.⁵⁶

In Figure 4, column E, it is seen that three clyses of 0.85 per cent saline solution, 12 cc. per kilogram, which provide an appropriate water intake, exceed the sodium chloride requirement by 320 per cent and provide no calories whatever.

If the clyses contain 2.5 per cent dextrose in 0 per cent sodium chloride solution (column F), sodium chloride still exceeds the requirement

FIGURE 3.

160 per cent, whereas the calories have been increased to only 14 per cent of the daily requirement. Therefore, the provision of more calories requires the intravenous infusion of some glucose. Since a continuous drip, such as given in column D satisfies the requirements of water, sodium chloride, calories and amino acids, resort to clyses together with small infusions in the provision of maintenance needs to adults should be avoided if possible.

What, then, is the rate at which these infusions should be administered? It has been suggested that only 10 to 12 gm. of dextrose can be oxidized per hour by an adult and that this rate prescribes a limit to the desirable rate of infusion.⁵⁷ If so, only 288 gm. of dextrose should be given a 60-kilogram adult in twenty-four hours. If this amount of dextrose is given in 2600 cc. of fluid, it means an 11 per cent solution of dextrose administered at the rate of 1.8 cc. or 32 drops a minute for twenty-four hours. Even if the rate of oxidation of dextrose by the infant is assumed to be double that of the adult, the limiting rate for a 5-kilogram

NEW HAMPSHIRE MEDICAL SOCIETY

PROCEEDINGS OF THE ONE HUNDRED AND FIFTY-THIRD ANNIVERSARY

House of Delegates, May 15 and 16, 1944 (Concluded)

Report of the Committee on Medical Economics

New Hampshire Physician Service

In conjunction with the officers of the Society, the committee has continued its efforts toward the setting up of a medical-service program in New Hampshire in accordance with the instructions given to the committee at the last regular meeting of the House of Delegates. Since then progress reports have been presented at two special meetings of the House of Delegates and the approval of the House secured at each occasion. The proposals of your committee on a medical-service program have now been put into concrete form as outlined below:

Present status. The New Hampshire Physician Service has been legally incorporated under the laws of New Hampshire, our committee, with the addition of Attorney Frank J. Alloway, acting as incorporators. The incorporators have selected a group of voting members of the corporation, and these in turn have elected a Board of Directors. Since the enabling act specifies that a majority of the Board of Directors shall be approved by the New Hampshire Medical Society, it will be the duty of the House of Delegates at this session to vote on the list of directors submitted to it.

Subscriber contracts and physician contracts have been drawn up and copies of these sent to each member of the New Hampshire Medical Society. The program has been explained and discussed before each county medical society by a member of your committee, and the signed contract of the individual physicians together with subscription toward a capital fund has been solicited. Another provision of the enabling act requires the participation of at least 50 per cent of the physicians in any given area before the plan can be put into operation in that area.

Organization of the corporation. The corporation consists of three classes of persons: voting members, subscribing members and participating physicians.

Voting members consist of not less than fifteen nor more than thirty members of the New Hampshire Medical Society and not less than fifteen nor more than thirty representatives of the general public, the numbers from the two groups being equal. The original voting members are elected by the incorporators and the body is then self-perpetuating.

A subscribing member is any person who subscribes to the capital fund of the organization.

A participating physician is any physician holding a license to practice medicine in New Hampshire who is a member in good standing of the New Hampshire Medical Society, and with whom the corporation has a contract under the medical-service plan.

The Board of Directors, consisting of not less than seven nor more than seventeen members, is elected annually by the voting members of the corporation. A majority of the directors must be approved by the House of Delegates of the New Hampshire Medical Society.

The Professional Committee, consisting of not less than three members of the Board of Directors and the majority of the committee being members of the New Hampshire Medical Society, has supervision over all medical aspects of the Plan.

Subscriber contract. Contracts are written on an indemnity basis whereby the subscriber receives a specified allowance against the bill rendered by the physician. Such allowances are made in accordance with a published schedule of benefits. It is to be emphasized that this is not a fee schedule. The physician's fee is arranged between the patient and the physician as at present, subject only to the moral obligation on the part of the doctor when dealing with a patient in the low-income group to set a fee approximately equal to the benefit allowed.

The surgical contract provides for the payment of the stated benefit in the event of surgical care received in home, office or hospital. In addition, an allowance of \$10 is made

for anesthesia for any one illness, one of \$25 for diagnostic x-ray examination, and one of \$15 for laboratory examinations in any contract year, it being provided that these diagnostic examinations must be directly related to the surgical condition.

Medical indemnity is provided as a rider to the surgical contract. It furnishes an allowance of \$2 for each office and hospital visit and \$3 for each home visit in any nonsurgical condition. The first two calls in any one illness are excluded, and not more than twenty-five visits are allowed to the subscriber per year, nor more than fifteen visits to a dependent. In addition, the allowance for x-ray and laboratory examinations is made available for medical as well as surgical conditions.

Physician contract. The physicians agree to provide services to subscribers under the contract, and the corporation agrees to reimburse them in accordance with the schedule of benefits. The physician further agrees that if the money available for the payment of physicians' bills is less than the total amount of the bill, he will accept a pro rata payment of the indemnity.

Capital fund. It is estimated that a capital of \$10,000 to \$12,000 will be necessary to meet initial costs and current expenses until the volume of insurance written is sufficient to cover expenses. This fund is being raised by the solicitation of loans that shall be unsecured and noninterest bearing, and payable at the discretion of the Board of Directors when the financial condition of the corporation permits. These loans are being solicited mainly from the members of the New Hampshire Medical Society.

Comments. The plan presented has been developing over a period of three years at the instigation and with the approval of the House of Delegates of the New Hampshire Medical Society. It is interesting to note that the American Medical Association and the National Physicians' Committee are now urging the establishment of medical-service plans by component medical societies.

In regard to the specific details of the plan proposed, the indemnity type of contract was decided on because it makes no interference with the present physician-patient relation, either professional or financial.

The feasibility of providing surgical and medical care in the hospital has been demonstrated by various plans now in operation. The advisability of extending surgical care coverage to the home and office is less widely accepted.

The inclusion of medical care in the home and office is frankly experimental. It has been shown by past experience in such plans that the majority of people are interested in protection against major illnesses that may be catastrophic for them, rather than in protection against minor, relatively inexpensive illnesses. Nevertheless, if the need for the provision of medical service for the low-income groups is to be fully met, complete medical coverage must eventually be provided. The medical coverage provided in the contract is an attempt to work toward this ideal. It is restricted in amount and it is sold only as a rider to the surgical contract in order to protect the financial stability of the corporation. It is hoped, however, that through this limited coverage experience will be accumulated on which to base further extension of subscriber benefits in the future.

It is to be emphasized that at the present time any medical-service plan must and should be to a certain degree experimental, if such a voluntary program is eventually to achieve any degree of success. This implies a readiness to change and adapt specific details in the light of experience accumulated as we go along. It is in this spirit that your committee has worked and will continue to work in the development of the program, and it is in this spirit that the plan should be accepted by the physicians of New Hampshire.

National Physicians' Committee

In view of the rather widespread divergence of opinion among members of the Society in regard to the program and

from 6 to 10:30 p.m. If a single infusion is given for only nine of the twenty-four hours, a slower excretion and more desirable utilization of the fluid infused may be obtained by administering more sodium chloride.

Until information pertaining to these and other factors concerned with the optimal utilization of parenterally administered nutrients is available, the prescription of the rate of infusion and composition of parenteral fluids for a given patient must reflect common sense, careful clinical observation and a tolerance indicative of an enlightened awareness of ignorance.

understanding about it. This plan does not interfere with doctor-and-patient relation. That is, the doctor would I in his bill for whatever he feels he is worth, whatever would be. The allowance to be made is a certain indemnity, which the schedule shows. But I can't see why that should be any difference in the patient-and-doctor relation.

The Massachusetts plan has been working out satisfactorily, a lot of these plans are good. Of course, I agree that if the medical profession could take care of all of these people satisfactorily, everything would be all right; but they are not satisfied. One of the strongest organizations is the labor union, and they are in favor of governmental control of medicine.

I feel that it would be a wise thing to try this plan, because we wait until the Government takes it over, we shall be late. If we wait until incomes drop down, we shall be too late. Of course, it is a pleasure to find people able to pay their bills. But as soon as the war is over, that is going to be different.

Dr. Robinson thought that the greatest question regarding the plan was whether it would actually furnish medical care to the low-income group. These plans had not been successful in reaching a sufficient number of people to make them really a satisfactory arrangement. One real problem was the failure of proper education regarding these plans. He added that the people want something, but they lack the proper education.

Dr. Batt said that there seemed to be a demand for the plan in his town. There was one industry here, and an effort was being made to have a prepayment plan of some sort. The workers intended to organize themselves without the assistance of the medical profession, and it seemed certain that the plan adopted would be the Blue Shield. Everyone, he said, seemed to agree that some plan was necessary for the low-income brackets.

Secretary Metcalf spoke as follows:

I went to Nashua to see Dr. Rock and various other men, because there was evidently widespread opposition there, which the committee had not encountered elsewhere. I was interested in the fact that the Nashua Medical Association had presented to other counties a set of resolutions opposing the Blue Shield. I put out my neck and asked them to put me on the program, not to argue the thing pro and con but to give them the facts and information.

It seemed to me after I got started that there weren't many men there who wanted information. In fact, I was told beforehand that the Nashua group had decided to bury the Blue Shield, and the barrage was heavy. The spark that set off the reaction in Nashua has not been mentioned tonight—the financial side of the plan. The Committee had evidently not emphasized sufficiently the fact that the stipends for medical and surgical care were allowances, because many men had the idea that there was a fee schedule, and that when an allowance of \$75 for an appendectomy was stated, this meant that no one could charge more than that for the operation, no matter how wealthy the patient was. And there were also other misconceptions related to the same subject.

The law that was passed in the General Court reads as follows, in part:

No license shall be issued to any medical service corporation until evidence is furnished the insurance company that at least 50 per cent of the physicians . . . are participating.

At the present time, 47 per cent of the eligible doctors in the State of New Hampshire have signed up, and there are four counties that have not yet been thoroughly canvassed. The signatures are still coming in, and by now probably 50 per cent of the doctors have signed up to participate in the plan.

Regarding the phrase "the area in which the corporation operates," I asked the Insurance Commissioner what that meant, and he said that the area in which the corporation operates is any medical center. It might be a county, or there might be several areas in the county. In other words, Nashua was a medical area, and Manchester was a medical area. Somersworth and Dover were medical areas. This being the case, we find that most of these medical areas have already signified by their votes that they favor the Blue Shield.

However, at the present time Nashua does not want it, and there is absolutely no reason why they should take it.

Some of the areas, like Newport and Claremont, have voted eleven to one in favor of it. It seems to me that any medical area, in accordance with the spirit and the letter of the law, is entitled to go ahead with the plan. Therefore, my feeling is that the House of Delegates, which has considered the subject at three general sessions and two special sessions, has no particular reason to backfire at the present time and attempt to throw the plan out of a county. I think it is worth trying out. It may not be a success. I hope that the effect of it will be to discourage the Wagnerites by showing the people that they can have decent medical care at a price that will not tap the payroll.

Dr. D. G. Smith said that Nashua was not alone in opposing the plan, and that the majority of the physicians in Manchester were also against it. As secretary of his county society, he reported that Dr. Metcalf presented the subject very well. There was a lengthy discussion, at the conclusion of which the Society voted 28 to 7 to reject the proposal of the Blue Shield. The Nashua Medical Society had voted unanimously in opposition to the New Hampshire Physicians' Service. He said that everyone appreciated the work that the Committee on Medical Economics had done, but that it was necessary to consider the attitude of the profession as a whole. He pointed out that there were only 400 practicing physicians in New Hampshire and that many of them were in the military services. He said it had been stressed that the plan should be postponed until the 125 or 130 men now in the service could have a chance to express their wishes about it. The plan must be sold to the doctors first, and if they did not want it, how could it be sold to the rest of the people? The National Physicians' Committee had stated that 25,000,000 people were now enrolled in the plan, but according to the statistics he had just heard, the number of people favoring various state plans totaled 800,000, not 25,000,000. In addition, there were other plans, such as that of the Farm Security Administration, which had quite an enrollment.

Dr. Sycamore stated that the larger figure included all types of service—Blue Cross, commercial companies and so forth.

Dr. D. G. Smith said that the demand for the plan in this state was not great. The Massachusetts plan went into operation in July, 1942, and the demand for it was decreasing. In New Hampshire, according to Dr. Sycamore's report, the need for the Farm Security Administration Plan was going down, since the number of families covered had been materially reduced.

Dr. Robinson said that that plan went into operation when the farmer was in need of it.

policies of the National Physicians' Committee during the last year, your committee makes no statement either in support or in opposition, deeming it advisable to leave this question to the discretion of each member.

Medical-Care Program for Clients of the Farm Security Administration

Because of the present favorable economic conditions the number of families participating in the Farm Security Administration Program has been materially reduced and the number of subscribers to the medical-care program in Grafton County and Cheshire County is insufficient to provide an adequate insurance base. This plan will be discontinued when the New Hampshire Physician Service becomes a functioning corporation, and coverage of this group will be included under the latter program.

LESLIE K. SYCAMORE, *Chairman*
R. W. ROBINSON
FRANCIS H. DUBE

Dr. Mullins, for the Committee on Officers' Reports, expressed the belief that this is the most important matter to come before the Society in many years. In view of its fundamental importance, and the necessity for making a correct decision, he said that it had not been deemed wise to make any specific recommendations except that the subject should be discussed thoroughly in the light of its assets and liabilities and without personal prejudice. It was felt that it was most important to maintain a united front. He added that the members of the Society should be willing to consider the points for and against this plan calmly and dispassionately, and then try to arrive at a common understanding, that acrimonious debate and criticism would lead nowhere and that judgment should be tempered by the fact that the decision reached might influence considerably the course of medical practice in the State for years to come.

Dr. Byron then spoke as follows:

I am definitely not in favor of any such plan, and I should like to open my argument with a challenge to those who think we should adopt it. I have asked several members about it, who have stated they were in favor of it, and the only answer I get is, "Well, it's a good thing."

It seems to me that it is a plan that will affect all branches of medicine by reason of the times in which we are practicing medicine. I think that it should be based on a better reason than just that "it's a good thing."

I am wondering if we aren't just a little bit overconscious of the Wagner Act and the Wagner-Murray-Dingell Bill, and of some of the reports sponsored by the National Physicians' Committee. Some of the reports have not been enlightening. I am wondering if, in adopting such a plan, we are not going directly into the path laid for us, and if we are not going to fall into the pitfalls that we don't want to fall into. If the plan fails, certainly we have a noose around our necks, and we are going to cry out for someone to pull the rope.

The plan does not begin to provide for every workman. Let us take the average workman, getting less than \$2000 a year; we are not going to help him very much. We shall usurp the powers we have established, and eventually we are going to lead ourselves right into the arms of socialized medicine.

Dr. McQuesten said that he thought the position of the Hillsborough County Medical Society was somewhat misunderstood by some of the men. There were certain things about the Blue Shield that were not wanted, but the argument was not necessarily against those. He took the position that

this service was not necessary, and that the argument in favor of it could not be seen.

A member stated that the practice of medicine is based on sound fundamentals. Most physicians had been going along on that basis and had made satisfactory arrangements, economically speaking, with their patients. He hated to see the medical profession going into the insurance business, and to see a split on principle.

Dr. Byron said that he thought the propaganda had made the members a little overconscious, and that they were probably assuming the defensive. He saw no justification for dealing with the situation in this way or for feeling this way about it. He added that there should really be no fear over this proposition; in fact, the act had been lying idle for some time. Dr. Fishbein had been heard to say on three different occasions that it was a threat and would disappear.

Dr. Sycamore then spoke as follows:

I have been asked the reason for such a program in New Hampshire. I think there is a definite need for an extension of medical service, because of the changing type of medical practice today. The economic burden has become greater. Fifty years ago, the physician used his own skill, and that was practically all. Today, there are so many highly technical procedures in both diagnosis and treatment that medical service is much more expensive — too much so for the average low-income patient to handle; yes, and more expensive than the physician and his fee. So that there is a definite need for a better distribution of the medical care that we have available.

There is a public demand that is growing in certain labor unions. For example, they have had a poll on this question and set up a criterion that shows a great and growing interest in this question.

It has been said that we can take care of our business ourselves. I agree. The reason why the plan is being instituted now is in the first place, that although there is no need of immediate alarm about the passage of the Wagner-Murray-Dingell Bill, most medical people believe that there is going to be some distribution of medical care in the near future, if not in the exact form of the Wagner Act, then in some form or another. At least we can be that much ahead of the possibility by making a procedure available that will be suitable to us, and we shall have something to say about what will be done, and not have it forced on us, whether we like it or not.

Another reason is this: even though the economic level of workmen is fairly high at the present time, we need experience to find out the possibilities and limitations, and we need to make experiments along this line.

As we have heard, plans have changed and plans differ, and this is the time to get some experience along that line. It will be useless to try to start a plan when the Government has passed some program of socialized medicine.

Dr. Jameson spoke as follows:

This strikes me as a very important question to consider. We know that if the states do not do something toward taking care of the low-income groups, the Government will make plans that may be more radical than the ones we are now familiar with.

We know that the general public is demanding some type of prepaid medical care. A poll showed that 75 per cent of the people wanted to have some type of medical care. In the Gallup Poll, the groups that were covered were the professional and semiprofessional people, farmers and farm managers, textile workers, clerical workers, salesmen and office and kindred workers.

It is generally believed that the general public is going to submit to some type of help in the matter of medical care. It does seem as though we could take care of this group, the low-income

as to the Blue Shield, some people could afford to pay a small fee to protect their families when they were working, but they could not afford to pay the fee when they were sick. He said that the question was not whether the physicians wanted this plan, but whether the people wanted it. If there was a public demand for it, he asserted it would come out in one way or another. The plan, if operated under supervision, should work well. Naturally, he said, this was just the beginning, and there might be mistakes and flaws but after some co-operation those could be corrected. The Society had already endorsed this plan in a legal manner and had given the committee the power to go ahead and form a corporation. That had been done, and 99 per cent of the doctors in the State of New Hampshire had already subscribed to it. He did not know how the Society could retract.

Speaker Dwinell pointed out that the motion before the house was that the Blue Shield be rejected, and suggested a standing vote.

Secretary Metcalf said that there were 114 men in the military services and that a letter and all the literature on the plan had been sent to every one of them. These were sent to the men's New Hampshire addresses. Possibly some of the letters had not been forwarded, but some of them evidently were because he had received one reply. Out of the other 350 odd members who are residents of the State, he got three replies. The one reply from the soldier said that he was heartily in favor of the plan, and that when he got back into civilian life again he would thank God it was there.

Metcalf added that this physician was a member of the Hillsborough County Society.

Dr. Mullins thought that it was unfortunate that the House was voting on a negative motion. As stated in the report of the Committee on Officers' Reports, it was felt that the situation should be dealt with positively, since the Society looked to the use of Delegates for positive leadership. The Delegates, he pointed out, were the elected representatives of the Society and represented the sentiment of most of the doctors in New Hampshire. He requested that the motion be withdrawn. Dr. Dwinell then withdrew his motion. Dr. Mullins then moved for a vote approving the action of the Committee on Medical Economics and accepting the plan of the principles of the New Hampshire Physicians' Service. This motion was duly seconded. Dr. Clough said there seemed to be too much arguing on both sides to pass or shelve the motion, and suggested laying it on the table for one year. He admitted that he had many conflicting views on the subject, but was at present strongly in favor of the motion, and said that he thought there were others present who felt the same way. He suggested that the motion should be worded so that if it were defeated it could be brought up again next year.

Speaker Dwinell called for a standing vote on Dr. Mullins's motion, and the motion was carried, with 4 dissenting votes.

Dr. Sycamore said that the law required that a majority of the Board of Directors should be approved by the House of Delegates. He therefore moved that the House of Delegates approve the Board of Directors. This motion was duly seconded by Dr. Dye and was carried.

The meeting then adjourned at 11:30 p.m. until 9 a.m., May 16.

* * *

The House of Delegates reconvened at the Hotel Carpenter, Manchester, on May 16, 1944, at 9:00 a.m., with Speaker George F. Dwinell, of Manchester, presiding.

The following members answered the roll call.

The President, *ex-officio*
 The Vice-President, *ex-officio*
 The Secretary-Treasurer, *ex-officio*
 P. R. Hoyt, Laconia
 Richard W. Robinson, Laconia
 W. J. Paul Dye, Wolfeboro
 Francis J. C. Dube, Center Ossipee
 Albert C. Johnston, Keene
 Richard Batt, Berlin
 Arthur B. Sharples, Groveton
 Leslie K. Sycamore, Hanover
 Howard N. Kingsford, Hanover
 Donald M. Clark, Peterborough
 R. E. Byron, Manchester
 Deering G. Smith, Nashua
 Clinton R. Mullins, Concord
 William P. Clough, Jr., New London
 Gerard Gaudrault, Concord
 Harry B. Carpenter, Portsmouth
 Fred Fernald, Nottingham
 Roland J. Bennett, Dover
 George G. McGregor, Durham
 Donald G. Moriarty, Newport
 Emery S. Fitch, Claremont (alternate for B. Read Lewin)
 George C. Wilkins, Manchester (alternate for Stillman G. Davis)
 Dr. Henry O. Smith, Hudson

Dr. W. J. Paul Dye, reporting for the Committee on Nominations, proposed three men for president: Fred Fernald, Nottingham; F. E. Wilder, Whitefield; and Cleon W. Colby, Exeter.

Dr. Dye then pointed out that there were two candidates for president from the same county, which was unconstitutional, and requested another nomination in place of Dr. Colby. The name of John Hunter, of Dover, was proposed and was added to the list of nominations for president.

On written ballot, Dr. Fred Fernald, of Nottingham, was elected president.

Dr. Dye then proposed three men for vice-president: John F. Gile, Hanover; Robert W. Holmes, Keene; and Edward C. Batchelder, Dover.

On written ballot, Dr. Gile was elected vice-president.

Dr. Dye then read the rest of the slate, as follows:

Dr. D. G. Smith read a passage from the report of the Board of Trustees of the American Medical Association relating to this subject, and then continued:

The American Medical Association has been urging these plans since 1943, but they have been watching them in the various states, trying to see what the best solution of the problem is. I don't believe it has yet been found. I don't believe this plan will help the low-income groups.

The question of payroll deductions will come up, and some companies will try to take care of their employees. But the employees in some places are quite upset because of the 20 per cent deductible income tax, and the social security, unemployment, Blue Cross and a lot of other deductions. Some even have deductions for life insurance, some for health and accident insurance. Whether or not employees will stand another deduction is a question.

The launching of the plan, in my estimation, is an admission of the need for it in New Hampshire. We take care of the indigent. If there is necessity for launching the Blue Shield at the present time and taking care of the medically indigent, that is one thing, and that is an argument for the Wagner Act and state medicine — in other words, it admits that the people in New Hampshire haven't been doing a good job; that there is a need for such a plan.

It was brought out in the Nashua discussions that we should not have the Society going into the insurance business. Private insurance companies are already selling insurance and taking care of the cost of medical care.

In closing, let me say that I think we should be careful in launching the boat; we should have it all built and solid, and we should have it in a place where we can launch it. It does not seem to me that we should launch the boat at this time.

Dr. Smith then moved that the New Hampshire Physicians' Service be not initiated at this time.

A member asked what the effect of the motion would be if it were carried, since he understood that the corporation had been legally formed.

Speaker Dwinell said that the people who had already accepted this plan are entitled to its service and could not be stopped by any vote.

Dr. Sycamore said he did not see how a few dissenters could presume to ask the House of Delegates to tell the members of eight counties who have already accepted the program that they should not do it.

Speaker Dwinell mentioned that he had heard no one say anything against the Blue Cross. If that had been so successful and had helped people out, why was not the Blue Shield going to help them out, too?

Dr. Robinson said that if criticism of the Blue Cross was wanted, it could be found in the records of five, six and seven years ago.

A member asked whether it was the general consensus that the Blue Shield was mainly desired as a protection against the possibility of socialized medicine.

Speaker Dwinell said that this was one reason why it was wanted.

A member suggested that the larger sections of the country that could not possibly finance any prepayment plan had been overlooked. He was referring to some of the places in the South.

Speaker Dwinell said that the plan was not intended to take care of the indigent patients who

would always be taken care of by the town or county, but was for those who had enough, but not save it.

Dr. Wilkins took exception to Dr. Smith's statement that the plan could not be undertaken until all the doctors were in favor of it, pointing out some developments in medicine had become real not because the doctors demanded them but because the public did. As examples he cited the cancer program in New Hampshire, which was actually initiated by laymen because they were interested in taking care of indigent cancer patients, and brought to the attention of the Legislature because the medical men were consulted, and the tuberculosis program, which was brought about by a lay group, the New Hampshire Tuberculosis Association and not by the medical profession. When the Blue Cross was first started, he said, the Eliot Hospital was the only hospital that agreed to it and subscribed to its provisions, and many of the other hospitals fought against it. Today, they were with it. As Dr. Robinson had said, when the Blue Cross was first introduced, the same objections and the same arguments were brought up against it as were being brought against the Blue Shield. When it proved a success, and so would the Blue Shield. This House of Delegates, he continued, had discussed this matter for three years. The committee had done an outstanding and forward-looking job and had brought something to the Society that was worth while. He said the plan ought not to be turned down, but should be given an opportunity to prove its worth. Medicine was going to be practiced differently, and all must accept it. This was one of the ways in which it would be practiced. The people, he asserted, want something to cover their unusual medical expenses; otherwise, the Government will take over this matter.

Dr. Fitch was appointed as alternate delegate in the place of Dr. Lewin, who had had to leave the meeting, and spoke as follows:

I should like to express myself in opposition to Dr. Smith's motion. I think that we should go on record in regard to this insurance question now. It would be too bad to lay it on the table for another year.

Dr. Wilkins has well expressed what I have in mind, namely, that the public is ready for this program and that they are looking for the medical profession to carry it through. It has been pretty well publicized, and the public wants to see it adopted.

In Claremont, the Sullivan Machinery Company adopted the Metropolitan plan of insurance, whereby employees pay a part of the premium and the company pays the balance, and it is very well accepted. The employees all carry private insurance.

Dr. Dye said that doctors as individuals would all like to continue practicing the way they are now doing, and felt that they had done a good job. The medical standards he said were better in this country than anywhere else in the world. Nevertheless, he added, the Wagner Bill was passed, and there is still a demand by many groups for medical insurance and medical practice.

the American Medical Association than did the of the delegates.

Dr. Smith said that the allotment of delegates to various states was based on the number of members in the state medical society — possibly one delegate to every nine hundred members, with the proviso that each state was to have at least one delegate.

He said he did not see the point of the resolution suggesting that each state should have a minimum of two delegates since this would make the membership undemocratic, the representation not being

according to the number of members. He moved that the matter be tabled, since it required no action by the House. This motion was duly seconded and carried.

Dr. Clark proposed a vote of thanks to the Manchester doctors for their cordial hospitality, and moved that next year the meeting of the House of Delegates be held in Manchester. This motion was duly seconded and was carried.

The second and final meeting of the House of Delegates was adjourned at 9:45 a.m.

CASE 30431

PRESENTATION OF CASE

First admission. A sixty-year-old woman was admitted to the hospital because of swollen joints.

The patient had had the usual childhood diseases, including measles, diphtheria, pertussis and scarlet fever. At nine years of age she had "St. Vitus dance." She was subsequently in good health, but at the age of twenty-two she had pain, swelling and tenderness in the left elbow for a short period. The following year, thirty-seven years before entry, and immediately following the birth of her second child, she developed migratory joint involvement, with pain, redness, tenderness and swelling lasting for six months. She was then asymptomatic until twenty-three years prior to entry, when following the birth of her fifth child, she again developed migratory joint pains. At that time a presystolic murmur and thrill were heard, as well as a loud apical first sound. The joint pains disappeared in two or three weeks. She was otherwise symptom free until two years prior to entry, when she had palpitation and dyspnea on exertion and was put on digitalis for several months. Four months before entry she developed sore throat, headache and general malaise, which persisted despite bed rest until two weeks before admission, at which time she experienced pain and swelling of the first and second metacarpophalangeal joints and the left ankle, as well as persistent pain and stiffness low in the back. She had some dyspnea on exertion but no fever.

*On leave of absence.

Physical examination showed a well-developed, well-nourished woman lying flat in bed and in no discomfort. There was slight edema of the left ankle. The thyroid gland was enlarged and showed a small tender nodule measuring 2 by 2 cm. in the left lobe. The left border of cardiac dullness was 10 cm. to the left of the midline. The sounds were of fairly good quality. There were apical systolic and diastolic murmurs, and a diastolic thrill. The pulmonary second sound was greater than the aortic. The lungs were clear. The abdomen was normal. The second metacarpophalangeal joints of both hands were swollen, red and extremely tender. Pain and tenderness were elicited on motion of the knees and ankles.

The blood pressure was 140 systolic, 80 diastolic. The temperature was 98.6°F., the pulse 96, and the respirations 20.

Examination of the blood showed a red-cell count of 4,610,000, with 90 per cent hemoglobin. The white-cell count was 6800. The urine and stools were normal. The uric acid was 2.1 gm. per 100 cc., and the sedimentation rate 1.21 mm. per minute. An electrocardiogram showed normal rhythm, with a rate of 85, a PR interval of 0.28 second, slight slurring of the QRS complexes, normal T waves and slight left-axis deviation. The basal metabolic rate was +39 per cent.

X-ray studies of the chest showed dense dullness at the right apex, with mottling below it. The right lung field was smaller than the left, especially at the apex. The heart was enlarged to the left and down.

The patient was put to bed. Hot compresses were applied to the hands and 0.65 gm. (10 gr.) of aspirin was administered daily. She felt much better and by the end of the first hospital week was symptom free. The sedimentation rate ranged from 1 to 2 mm. per minute, with a final drop to 1.1 mm. per minute on the thirtieth hospital day. On that day an electrocardiogram showed a rate of 85, with a PR interval of 0.22 second. She was discharged at the end of the fifth hospital week.

Final admission (nine years later). Following discharge the patient apparently remained well and able to work every other day until about four years later (five years before entry), when she was seen in

Secretary-Treasurer: Carleton R. Metcalf.
Councillors:

(Two elected annually for five years)

Speaker of House of Delegates: Ralph W. Tuttle, Wolfeboro.
Vice-Speaker of House of Delegates: Deering G. Smith, Nashua.
Delegate to A. M. A. 1944-45: Deering G. Smith, Nashua.
Alternate Delegate, 1944-45: Emery M. Fitch, Claremont.
Necrologist: Henry H. Amsden, Concord.

STANDING COMMITTEES

Advisory Committee on Jurisprudence: Clifton S. Abbott, Belknap County; W. J. Paul Dye, Carroll County; John J. Brosnahan, Cheshire County; Richard E. Wilder, Coos County; John F. Gile, Grafton County; David W. Parker, Hillsborough County; Robert J. Graves, Merrimack County; Samuel T. Ladd, Rockingham County; Jeremiah J. Morin, Strafford County; Henry C. Sanders, Jr., Sullivan County; Carleton R. Metcalf, Concord, Chairman.

Amendments to Constitution and By-laws: W. J. Paul Dye, Frederick S. Gray, Ralph N. Jones.

Child Health: Colin C. Stewart, Jr., B. Read Lewin, Franklin N. Rogers.

Control of Cancer: George C. Wilkins, Ralph E. Miller, George F. Dwinell.

Maternity and Infancy: Robert O. Blood, Benjamin P. Burpee, Marion Fairfield.

Medical Economics: Leslie K. Sycamore, Richard W. Robinson, Francis J. C. Dube.

Medical Education and Hospitals: John P. Bowler, James W. Jameson, Herbert L. Taylor.

Medical Preparedness: Deering G. Smith, Ezra A. Jones, Carleton R. Metcalf.

Mental Hygiene: Benjamin W. Baker, John B. McKenna, Simon Stone.

OPA Assistance: Charles H. Parsons, Alexander Barbeau, Philip McQuesten.

Public Health: Harris E. Powers, Anthony E. Peters, Clinton R. Mullins.

Public Relations: The President, the Vice-President, the Secretary-Treasurer, Robert J. Graves, Joseph N. Friborg.
Publication: Carleton R. Metcalf, John F. Gile, Emery M. Fitch.

Scientific Work: Carleton R. Metcalf, Frederic P. Scribner, Sven Gundersen.

Tuberculosis: Robert B. Kerr, Richard C. Batt, Charles H. Parsons.

The Secretary was instructed to cast one ballot for the remainder of officers and committee members, as nominated; this was done, and all were declared duly elected.

Report of the Committee on Memorials and Communications

The committee has two matters to take up. We have one communication from the Office of Price Administration in connection with the rationing of special food for the sick people. The OPA wants the Society to appoint a committee to see that the sick person really is sick, and really needs special food rations. They want to see that the sick people have what they should have, but they want to understand that the person really needs it.

The committee is in favor of this proposition from the OPA and recommends the following committee: C. H. Parsons, Concord; Alexander Barbeau, Manchester, and Philip McQuesten, Nashua.

I also have a communication from the Medical Association of Southern California relative to the House of Delegates of the American Medical Association. It seems that the minimum number of delegates from a state is one, the more populous states having twenty or more delegates. The recommendation from the Southern California Medical Association is as follows:

BE IT RESOLVED, That the House of Delegates of the Southern California Medical Association petition the House of Delegates of the American Medical Association to amend its constitution and by-laws so that the minimum number of delegates to which each constituent organization is entitled shall be two, instead of one.

In other words, each state would have at least two delegates to the American Medical Association instead of one.

Dr. McGregor did not understand how the OPA plan was going to function. He asked whether, for example, if he had a diabetic patient he must consult somebody in Nashua.

Dr. Kingsford stated that the OPA wanted a committee appointed by the Society to which the OPA could turn if the demand was not authentic or seemed unreasonable.

Dr. McGregor asked if the committee would examine the records at Nashua to see if he was right.

Dr. Kingsford said that he did not understand it in that way. He explained that the OPA had many applications from people who were not licensed doctors, and needed someone to check them. He did not believe that the OPA sought to question anything that a regular physician did.

Dr. Robinson said that this was being done, and that prescriptions of physicians in regard to food thought necessary in particular cases were being questioned. He reported that he prescribed a diet for a patient with a severe nephrosis, and that the OPA wrote to him saying that it could allow his protein diets only for tuberculosis.

Dr. Kingsford said that the Society should have a committee to back up its members.

Secretary Metcalf said it was just this type of case that the OPA wanted to refer to a group of three doctors. He said that there were relatively few cases where the matter came into question at all, but that every once in a while the OPA got a case in which it did not know whether to say "yes" or "no." It would like some responsible committee from the New Hampshire Medical Society to which it could refer such a case for advice, not wanting to pass on it themselves for fear that whatever the said would be unjust. According to the OPA there were only two or three such cases a month.

Dr. Sycamore moved that the committee, if named, be constituted to co-operate with the OPA. This motion was duly seconded and was carried.

Speaker Dwinell said that the second part of the committee report should be discussed by Dr. D. Smith, since he knew more about the constitution.

olic murmur was very faint. The extremities were cold. There was ptosis of the right eye, and both pupils were dilated and fixed to light. The right arm seemed limper than the left. No marked changes in reflexes were noted. The blood pressure was 110 systolic, 70 diastolic. The temperature was from 102 to 99°F. The radial pulse was 80. An electrocardiogram revealed auricular fibrillation with a rate of 120 and some change from the previous tracings, in that T₂ as well as T₁ had become inverted, with depression of ST₄ and inversion of T₄. On the following day the right arm became cold, pulseless, blue and flaccid. The right leg was weaker than the left. The tendon reflexes were equal. The blood pressure was 156 systolic, 88 diastolic, in the left arm. There were signs of consolidation in the left lung base. Breathing became stertorous, the coma deepened, the temperature rose to 102°F., and the patient died on the ninth hospital day.

DIFFERENTIAL DIAGNOSIS

DR. T. DUCKETT JONES: This case is long on paper and in years. At a young age the patient's rheumatic story began with Sydenham's chorea and followed a characteristic pattern in that heart disease did not develop until many years later after definite attack of rheumatic fever. We have found that, in a group of reasonably well-followed chorea patients, the incidence of heart disease without other manifestations of rheumatic fever is extremely low, not over 18 per cent, after a period of eight or ten years. The incidence of heart disease in the total chorea group (including other manifestations of rheumatic fever) is about 50 per cent, as opposed to 70 per cent or more in rheumatic-fever patients without chorea.

The joint involvement after the birth of her second child seems characteristic of rheumatic fever. In our experience, patients developing rheumatic fever within three or four weeks of the termination of pregnancy have usually had active rheumatic fever in the recent past, that is, within two or three years of the pregnancy. In this case, rheumatic fever occurred one year prior to the episode after the second pregnancy. No information is given relative to any relation between the first pregnancy and the initial attack of rheumatic fever. Fourteen years elapsed, however, between the second and third clinical attacks of rheumatic fever, and the latter followed the fifth pregnancy. Since heart disease was noted initially during this attack, one wonders if mild or subclinical rheumatic fever may not have occurred at some time during the latter part of the fourteen-year period. This would help explain the interval between the two early attacks of rheumatic fever and the finding of mitral stenosis during the third attack many years later. Since presystolic murmurs are easily heard late in pregnancy, it seems probable that, if present, it would have been heard during the third or fourth preg-

nancies. Where there is definite evidence of rheumatic fever even without heart disease we advise the patient not to become pregnant until two or three years after the termination of the active disease.

In view of the history and findings on the first admission, we are forced to accept the fact that, at the age of sixty, after an interval of twenty-three years without clinical attacks of rheumatic fever, there was a rather characteristic recurrence of rheumatic fever. This is a rather unusual story, in fact, I believe that it is rare. It did follow a definite story of sore throat, and one wonders if intimate exposure to the hemolytic-streptococcus infections of her children and later of her grandchildren may not help explain the pattern of illnesses. There were apical systolic and diastolic murmurs and a diastolic thrill. One would presume that there was a presystolic phase (crescendo) of the diastolic murmur and that the diagnosis of mitral stenosis was justified. The sedimentation rate and the electrocardiographic findings are entirely in keeping with active rheumatic fever.

The high metabolic rate was probably due to the active disease rather than to any effect of the small nodule in the thyroid gland.

We do not know how long the active rheumatic fever continued. This adult of sixty certainly had the disease for a few months: she had it for some time prior to hospital admission and it continued at the time of discharge, as shown by the sedimentation rate and the long PR interval.

On second admission she gave a story of hemoptysis. There are several causes of hemoptysis in a rheumatic-fever patient. On rare occasions, one sees it in young people even without mitral stenosis. During active rheumatic fever, it occurs but is rare. More frequently it is associated with acute, left-sided failure in patients with old and severe rheumatic heart disease, especially mitral stenosis. This patient, however, did not have such an acute episode. There is a reasonably large group of patients in whom hemoptysis occurs purely on the basis of mechanical failure, without evidence of active rheumatic fever. I recall a few patients being followed in the Out Patient Department who repeatedly came back to the Emergency Ward or at times were admitted to the hospital because of repeated hemoptyses and who had absolutely normal laboratory findings. One wonders if this is the result of pulmonary-artery disease comparable with that reported by Parker and Weiss¹ in which there were changes in the pulmonary vessels of mitral-stenosis patients similar to those seen throughout the body in patients with arteriolar sclerosis. These authors call attention to the similarity of the changes in vessels seen in nephrosclerosis. To me it seems likelier that the majority of these patients have either small pulmonary infarcts or pulmonary thrombi, rather than actual arterial disease, as the

the Emergency Ward following repeated episodes of hemoptysis over a period of twenty-four hours, amounting in all to about half a cupful of blood. She had had no chest pain, fever or chills. Examination showed the lungs to be clear, with bronchovesicular breath sounds in the right paravertebral region posteriorly. The left border of cardiac dullness was 8.5 cm. to the left in the sixth space. An apical, rumbling, crescendo, presystolic murmur was heard. The blood pressure was 180 systolic, 90 diastolic. The temperature was 99°F., the pulse 72, and the respirations 20. X-ray examination of the chest showed definite increase in the size of the heart since the previous examination. The enlargement was on both sides, and there was prominence of the pulmonary conus. The hilar shadows were slightly increased, and there was a marked increase of the linear markings, with areas of increased density scattered throughout both lung fields. She was advised to take it easy and rest in bed and to return in one month.

She was not seen for the next five years, except for the treatment of varicose ulcers of the leg, which healed slowly, but was apparently asymptomatic until five months before the final admission, when she noted moderate dyspnea which came on when she was out of doors or climbing but not doing strenuous work around the house. She had had occasional attacks of palpitation and felt extremely nervous. She experienced difficulty in swallowing, consisting of a sensation of discomfort, which extended over the anterior surface of the neck, and occasionally felt as if the food stuck. Examination in the Out Patient Department three months before entry revealed essentially the same findings as before. The blood pressure was 198 systolic, 118 diastolic. The pulse was regular at 80. The sedimentation rate was 0.74 mm. per minute, and the hematocrit 43. She was advised to return for admission, but refused. The dyspnea progressed in severity.

Three days before entry the patient developed weakness and general malaise. She became increasingly dyspneic, anorexic and cyanotic. Shortly before admission she experienced a smothering sensation, with marked dyspnea and orthopnea. She had no peripheral edema, chest pain, chills or fever. She was referred to the hospital after her physician had been unable to control the attack with morphine.

Physical examination showed a well-nourished, dyspneic, cyanotic woman. The neck veins were slightly distended. The lungs were resonant. There were decreased breath sounds and many moist rales in both lung fields posteriorly. The left border of cardiac dullness was 10 cm. to the left of the midline in the fifth space. There was auricular fibrillation at a rate of 120. The heart sounds were weak. A systolic murmur and a rumbling mid-diastolic murmur were heard at the apex along the left sternal border. The liver edge was felt 2 cm. below the right

costal margin. A healed varicose ulcer and st dermatitis were present on the left leg, but there was no frank pitting edema.

The blood pressure was 120 systolic, 80 diastolic. The temperature was 99.2°F., the pulse 120, and respirations 28.

Examination of the blood showed a red-cell count of 3,960,000, with 12.8 gm. of hemoglobin. The white-cell count was 10,400, with 85 per cent neutrophils. The urine gave a specific gravity of 1.020 and a + test for albumin; occasional red, white epithelial cells were found in the sediment. The nonprotein nitrogen was 28.5 mg. per 100 cc., the serum protein 6 gm.

X-ray films of the chest showed marked enlargement of the heart, the left border almost touching the axilla. The left main bronchus seemed to be elevated, probably owing to enlargement of the auricle. The hilar vessels were slightly engorged. There were linear areas of increased density extending upward from the hilar vessels to the apices, marked on the right.

The patient was given oxygen and 4 cc. of Cedonid intravenously, followed by 0.2 gm. (3 gr.) digitalis and 2 gm. (30 gr.) of ammonium chloride by mouth, with marked improvement. On the second hospital day the pulse rate fell to 56, with a subsequent rise to 80 within a few hours, and then to 100, where it remained. She was given the usual diuretic regime of ammonium chloride three times a week, with Mercupurin. An electrocardiogram on the second hospital day showed auricular fibrillation with a rate of 70. T_1 and T_2 were low, ST_1 and ST_2 depressed, and T_3 flat and T_4 diphase. There was left-axis deviation. The urinary output on the second hospital day rose to 2250 cc. on a fluid intake of 1000 cc. and thereafter equaled the intake. The temperature varied between 100 and 101°F. The white-cell count ranged from 7500 to 10,500.

On the third hospital day the patient was awakened from sleep by a sudden, severe, precordial pain which was worse on deep breathing. Examination showed fine crackling rales at both lung bases. The heart was the same as before. There was tenderness in the left calf. Homans's sign was negative. The blood pressure was 180 systolic, 90 diastolic. The pulse was 100, and the respirations 30 and labored. An electrocardiogram revealed auricular fibrillation with a rate of 100. T_1 was inverted, ST_2 and ST_3 deeply depressed, T_2 upright, and T_3 diphase; Lead 4 was normal. X-ray studies of the chest showed no change. A bilateral femoral ligation was performed. The pain apparently disappeared but the patient continued to run a low-grade fever and was moderately dyspneic and orthopneic. On the seventh hospital day she became rather suddenly unresponsive. Examination showed a marked change in the heart sounds, which were not tic-tac in quality. The systolic murmur could not be heard. The di-

The chances of this are rare. I believe that one would be safer to stick to rheumatic heart disease as the basis of her demise.

I presume that it is unlikely that she had active rheumatic fever at the time of death. The usual pattern of fatal progressive rheumatic heart disease results in death at an earlier age, usually fifteen or twenty years after the initial attack. I should say that there is little chance that she had Aschoff bodies; this is possible, however, since she had rheumatic fever as late as the age of sixty. I do not believe that it is necessary to predicate active rheumatic fever during her terminal illness. We know that in old people the onset of auricular fibrillation is not necessarily associated with active rheumatic fever, but it is frequent in children and young adults.

I explain the entire picture on the basis of rheumatic heart disease with extensive thrombi in the heart. There may have been some evidence of old pulmonary infarcts or thrombi. Emboli were present in the brain and the right arm at the end, and probably in the coronary arteries. The terminal coronary accident may have been on this basis rather than due to straight arteriosclerosis.

DR. LAURENCE L. ROBBINS: These films are not particularly helpful. They were taken at the time of the final admission. The patient apparently stayed out of the hospital long enough so that the early films were destroyed, and we have no way of following the course of the disease.

There is not much question about the cardiac enlargement. The left ventricle and left auricle are apparently enlarged, and there is some elevation of the bronchus with widening of the carina. I do not see anything that suggests recent infarction, at least within the lung. There is an old process in the right upper lobe to which some consideration ought to be given; it looks now like an old, tuberculous, bronchiectatic affair. There is one shadow in the right lower lung field that possibly represents an old healed infarct; it is simply a scar.

DR. JONES: When was this film taken?

DR. ROBBINS: Two days before she died.

DR. CONGER WILLIAMS: The electrocardiographic changes are not at all diagnostic of a coronary episode. One often sees quite a marked change in the terminal stages. I do not believe that one can conclude that these changes were the result of infarction. T-wave changes are present, but they are not sufficiently clear cut to be sure about them.

DR. CASTLEMAN: The electrocardiogram taken immediately after the episode was interpreted as being consistent with a recent anterior occlusion.

DR. WILLIAMS: It is a possibility, but I do not believe that one can say that it is diagnostic.

CLINICAL DIAGNOSES

Rheumatic heart disease, with mitral stenosis and regurgitation.
Auricular fibrillation.

Congestive heart failure.
Acute pulmonary edema.
Pulmonary embolus?
Cerebral embolus.
Pneumonia, left lower lobe.

DR. JONES'S DIAGNOSES

Rheumatic heart disease.
Mitral stenosis.
Auricular fibrillation.
Congestive heart failure.
Old pulmonary infarcts or emboli?
Coronary closure (? embolic).

ANATOMICAL DIAGNOSES

Rheumatic heart disease.
Endocarditis, subacute and chronic, rheumatic: mitral and aortic valves, with stenosis of mitral valve.
Atheromatosis of aorta and coronary arteries, marked.
Thrombosis of anterior descending branch of left coronary artery.
Myocardial infarction: anterior wall of left ventricle and anterior portion of septum.
Cardiac hypertrophy.
Mural thrombus: left auricle.
Embolism of axillary artery, with early gangrene: right forearm and hand.
Bronchopneumonia: right lower lobe.

PATHOLOGICAL DISCUSSION

DR. CASTLEMAN: The autopsy showed an enlarged heart (480 gm.), but one not so large as might have been expected in a patient who had had heart disease for many years. There was a mitral stenosis of moderate degree, and slight aortic disease. We could not get two fingers into the mitral valve. On the mitral valve there were small, fairly firm vegetations measuring 0.5 to 1 mm. in diameter, and above there was a mural thrombus in the left auricle. On microscopic section the valve showed an active rheumatic process; there was no evidence of palisading, but a lot of cellular infiltration and granulation tissue. The lesion was definitely older than four years, thus indicating that there had been mild rheumatic activity most of the time. The myocardium showed no Aschoff nodules. There were a few suggestive areas, and perhaps with more sections we might have been able to find a few. In the anterior wall of the left ventricle we found hemorrhagic discoloration; there was no mural thrombus over it, but it appeared softer than the rest of the myocardium and our sections show that it was a recent infarction. The coronary arteries were moderately sclerotic and calcified, and in the descending branch on the left we found evidence of recent thrombosis. I am fairly certain that it was a thrombus and not an embolus, because I do not believe

basis of their hemoptysis. Such patterns are variable and difficult to be sure of unless one has enough evidence to make a diagnosis of pulmonary infarction, or unless acute pulmonary edema exists.

No electrocardiogram was made at the time of the second admission. It might have helped in delineating the cause of the hemoptysis.

I presume that this patient had difficulty in swallowing—a sensation of discomfort and so forth—on the basis of esophageal distortion, which is frequent in extensive rheumatic heart disease with left auricular enlargement. There is some x-ray evidence that she had such a syndrome.

"The blood pressure was 198 systolic, 118 diastolic." This is the first time that there was increase in the diastolic pressure, and it may be significant.

A paroxysmal arrhythmia may have caused some of her trouble but there is no clear-cut indication of it.

At the time of the last admission she was sixty-nine, a ripe age for a patient with rheumatic heart disease. Heart disease was known to have been present for thirty-one years, and she lived for sixty years after chorea and for forty-seven years after the first clinical attack of rheumatic fever. At sixty-nine she had an acute episode that was severe enough to bring her to the hospital. Despite the frequent admonishment to return, she was not regular in following advice and came in only when she was distressingly in need of help.

At that time, so far as we have proof, there had been no frank active rheumatic fever since the age of sixty, although it is possible that she had active rheumatic fever at the age of sixty-four. The chief features of her difficulties at the age of sixty-four, however, were more in keeping with a heart that is failing than with rheumatic fever with failure on the basis of the active infection. I know that Dr. Castleman wants me to commit myself whether or not she had active rheumatic fever at the end, in addition to other diagnoses.

For the first time she was fibrillating, many years after known mitral stenosis.

The later findings may be a red herring in view of the developments. I might point out here that she had good basis for a thrombophlebitis, which has to be taken into consideration. She had a distinct drop in blood pressure, which usually happens at the onset of fibrillation. So long as her pressure remained elevated she did reasonably well. This has been pointed out by Dr. S. A. Levine² as being usual in patients with mitral stenosis. The question whether or not she had a pulmonary infarct at that time is pertinent. I presume that this was probable and that it accounted for the change on the third hospital day. The electrocardiogram showed partial digitalis effect. She had an acute episode with not only pain in the chest but something happening in the leg. One must think seriously of thrombophlebitis.

It is rather surprising that the blood pressure did not drop at the time of the acute episode. She did,

however, have labored respiration and pain in the left calf. It is perfectly obvious that the electrocardiogram did not suggest a pulmonary infarct as an explanation of what had happened, and it is stated that, although x-ray examination showed no change, a bilateral femoral ligation was performed. That means, of course, that they considered pulmonary infarct as being likely, with the legs as the source, which is rather surprising to me in the presence of obvious, severe, rheumatic heart disease with failure that had been present prior to the onset of the acute episode. Severe rheumatic heart disease with failure presents unusual patterns, and one does not necessarily have to explain the clinical syndrome on the basis of pulmonary infarction or on that of another possibility, namely, a coronary accident. It is obvious that there was also a cerebral infarct. There was a distinct change in electrocardiogram which I hope Dr. Williams will comment on and which to my mind—I talked this over with Dr. Wheeler before I came in—strongly suggests that there was an accident involving the coronary system. I do not see how one can avoid this interpretation under the circumstances. The questions are, Why did it occur? and, On what basis can it be explained?

In summary, here is a story of rheumatic fever and heart disease of fifty to sixty years' duration, with an obvious decrease in cardiac reserve for a period of three, four or perhaps five years. Prior to the hemoptysis, at the age of sixty-four, a definitely low cardiac reserve existed. The sudden onset of fibrillation, with the development of failure and an unexplained acute episode a few days later, was the crux of the terminal situation. The patient had pain, a drop in blood pressure, electrocardiographic changes and evidence of multiple emboli. The question is whether or not she had a typical coronary accident. She was a sixty-nine-year-old woman and certainly this might not be unexpected, and the embolic phenomena could have come from a coronary accident. I find this rather hard to believe inasmuch as she had had obvious heart disease and a distinct decrease in cardiac reserve over a period of a few years. We know that in the failing rheumatic heart, particularly in one that fibrillates, embolic phenomena are frequent. We also know that in active rheumatic fever with heart failure embolic phenomena are rare. In some patients with failing hearts and mitral stenosis, extensive intracardiac thrombi are found at autopsy. Such thrombi are often extensive and may even extend into the pulmonary tree. There has to be some explanation for the arterial phenomena, however, and it seems to me that they fit into one pattern—an elderly woman with severe heart disease, cardiac failure and embolic phenomena. I therefore suggest the rare occurrence of coronary embolism. That may not have been the mechanism, but it could perfectly well explain the coronary accident. Ordinary arteriosclerotic disease may well have been the basis, but it seems to me that

DR. BARNEY: In other words the urine contained a few red cells. The fact that it contained white cells might have been due to the fulgurations. It does not throw a great deal of light on the question.

I shall look at the x-ray films.

DR. MILFORD SCHULZ: This is the intravenous pyelogram. In this twenty-minute film you can trace the ureter down to the bladder. It is a perfectly normal ureter as regards size and course.

DR. BARNEY: The record states that the shadow of the bladder was irregular across the dome and somewhat more depressed on the right side than on the left. They are referring to this depression. One often sees that; it is of no consequence. It is often due to the fact that the lower sigmoid presses on the bladder. I cannot see, at this distance at least, any evidence of a soft-tumor shadow on the right side, unless there is something there that may be fecal matter.

On the second hospital day an operation was performed. In a case with a story like this, one would not operate on the second hospital day without doing something in the way of cystoscopic examination. It may have been done outside. Is there anything further in the record?

DR. SNIFFEN: Cystoscopy was done at the outside hospital just before entry, at which time the granular lesion was observed. He was sent in for operation.

DR. BARNEY: There are a few diagnostic possibilities to be considered. Cystoscopy at one time showed what seemed to be a papilloma at the orifice of the left ureter. When he was cystoscoped again there was an area surrounding the ureter that was red, granular and firm and covered an area 1 or 2 cm. in diameter. This does not sound like a description of a papillary tumor of the orifice of the ureter or of the bladder. If it is true that he had a papillary tumor of the left renal pelvis, one can imagine that what he had five years afterward was an implant from the papillary tumor in the pelvis into the ureter or along the course of the ureter. It may have grown more or less the length of the remaining ureter, or it may have grown just around the orifice of the ureter, or it may have been in the ureter long enough to get outside the ureter and form a tumor in the pelvic region. We not infrequently see a papillary tumor near the orifice of a ureter, or sometimes within it, and not thinking of the possibility of a kidney tumor above, we fulgurate the lesion and think that we have done our job. An intravenous or retrograde pyelogram should show whether there is a tumor in the kidney above it. If not, one is dealing with a tumor of the ureteral orifice, which is an entity in itself; whereas if there is a tumor in the kidney, it is a waste of valuable time to fulgurate the tumor at the orifice of the ureter.

I should like to know a little more about the urine from the right kidney. It is true that it secreted the dye normally, that the ureter was all right and that the kidney itself at first glance looked fairly good. It is a faint film. I should rather see a more powerful secretion of the dye. This does not look normal to me: the middle calyx is divided into two parts, and the upper calyx is slightly dilated and seems to have a somewhat different density. There is considerable density in some parts and less in other parts, and here the appearance is bifid. So I am not at all sure that something was not going on, possibly a neoplasm, in the right kidney, which would cause the hematuria. Of course, it is evident that he had, or did have, a neoplastic condition at the orifice of the left ureter. So we come down to the question whether this was a residue, so to speak, from the tumor of the renal pelvis on the left, which, after a long period of quiescence on the part of the tumor, finally started up and produced the symptoms and signs that we have been told about. If that was the case, I am surprised that there is not some mention of a mass felt by abdominal or rectal examination, or evidence in some way that there was tumor along that ureter. Nothing was apparently done to investigate the stump of the left ureter. There is nothing here to indicate that a catheter was passed into the ureter on the suspicion or chance that there might have been a papillary tumor sprinkled along its course for a greater or less distance. If that had been done we should be able to say whether there was a clean ureter with trouble at the orifice, which in itself might have been due to the tumor of the kidney pelvis that had been removed.

I also wish that a retrograde pyelogram had been done on the right kidney. We often find that an intravenous pyelogram does not give all the necessary information. There is enough suspicion aroused by the appearance of the right kidney to warrant a retrograde pyelogram. There is no evidence that this was done. Attention was focused on the orifice of the left ureter, and the patient was operated on two days after he came in.

I believe that we can rule out tuberculosis, stone and nephritis, and it therefore comes down to a tumor of the lower end of the left ureter with extrusion out into the bladder, to some growth around the ureter in that region or to some lesion in the right kidney, which, so far as I can find out, was not further investigated. My first diagnosis is residual papillary tumor of the lower end of the orifice of the left ureter and of the bladder around the orifice of the ureter. My second guess would be a pathologic lesion in the right kidney, which had not been adequately studied. The fact that the patient was operated on forty-eight hours after he came into the hospital indicates that the surgeon

that an embolus could have gone through into the area where the occlusion occurred.

There was no recent infarction of the lung, but there was evidence of old scarring in several places, such as might have occurred with previous infarction or perhaps rheumatic pneumonia. I should favor rheumatic pneumonia rather than infarction. The arterioles in many places were markedly thickened, and the media showed hypertrophy of the muscle cells.

The liver showed a mild degree of failure.

DR. JONES: Do you think it likely that, if she had not had the coronary accident, she would have followed the pattern of an early fibrillator and have gone on for many years?

DR. CASTLEMAN: She did have a mural thrombus in the left auricle.

DR. JONES: Yes; but probably all fibrillators do at the onset. They need not be extensive.

DR. JAMES NEIL: Were there any emboli or thrombi in the major cerebral vessels to explain the paralytic symptoms?

DR. CASTLEMAN: We have not yet examined the brain; she probably had small emboli.

CASE 30432

PRESENTATION OF CASE

A forty-six-year-old man entered the hospital because of hematuria.

The patient had been in good health until nine years before entry, when he first noted blood in his urine. The bleeding was intermittent and painless. It would continue for two or three days and stop for one to four weeks. There were no clots. He was seen at a community hospital, where a left nephrectomy was performed for a papilloma of the left renal pelvis. Following the operation he was asymptomatic for five years, at the end of which time hematuria recurred. He was cystoscoped; and a tumor in the region of the left ureteral orifice was fulgurated. He subsequently had ten or twelve recurrences of hematuria, with repetition of the treatment. Following each treatment he was asymptomatic for two to five months. He was again cystoscoped. The left ureteral orifice and a surrounding area 1 to 2 cm. in diameter were firm, slightly red and granular; no definite papilloma was seen.

Physical examination showed a well-developed, well-nourished man in no distress. The lungs were clear. The heart was not enlarged. The sounds were of good quality and regular. A soft, blowing, Grade I aortic systolic murmur was heard, which

was transmitted to the neck. The abdomen was negative. Rectal examination revealed a small, firm, resilient, smooth, symmetrical prostate. The right and left lobes measured 2 by 2 by 2.5 cm., and the margins were sharp; the median sulcus was shallow, and the gland movable.

The blood pressure was 135 systolic, 80 diastolic. The temperature was 98.6°F., the pulse 96, and the respirations 20.

A blood Hinton test was negative. The urine was cloudy, with a specific gravity of 1.016 and a + test for albumin; the sediment contained occasional red cells, 20 white cells and much debris per high-power field.

An intravenous pyelogram showed prompt excretion of the dye by the right kidney, which had a normal pelvis and ureter. The left kidney was absent. The bladder shadow was somewhat irregular across the dome, appearing somewhat more depressed on the right than on the left. No definite filling defect could be visualized. The bladder emptied normally. Plain films of the abdomen were negative. X-ray films of the chest were negative except for some evidence of emphysema.

On the second hospital day an operation was performed.

DIFFERENTIAL DIAGNOSIS

DR. J. DELLINGER BARNEY: The initial hematuria apparently was due to the tumor of the left renal pelvis, which was relieved by nephrectomy. The strange part of it is that the patient went without symptoms for five years and then had recurrent intermittent hematuria. That again suggests a tumor, possibly in the other kidney, bladder or ureter. It might also have been due to stone in the remaining kidney or ureter or to tuberculosis, but the latter is not likely because tuberculosis is infrequently attended with gross hematuria. The abdomen was said to have been negative, which is rather important. The statement about the prostate aroused my interest because it seems to be the description of a normal prostate, both in size and consistence. It does not say so, but I suppose that nothing was found around the prostate or at the base of the bladder to suggest a mass of some kind that involved the tissues around the bladder.

The blood pressure appears to rule out the possibility of a hematuria due to nephritis. The fact that he had a history of intermittent hematuria with only occasional red cells does not mean much because the examination might have been done during the interval.

There is no mention of a urine culture, and I should like to know whether it was done.

DR. RONALD C. SNIFFEN: The culture showed colon bacilli.

DR. BARNEY: Was it bladder urine or urine from the right ureter?

DR. SNIFFEN: It does not say.

fession, as such, and as represented by its society journals has the record, to date, of having held itself aloof from those party gyrations, which present no edifying spectacle at this stage of the administrative cycle.

Medicine, with no political axe to grind, although year by year it is growing more acutely conscious of its lack of such a weapon for defensive purposes. is increasingly in danger of becoming the victim of the ardent axemen of either party. Accustomed from time immemorial to minding its own business, and to being quite slow about it, it has been marked as a suitable subject for reform by those who specialize in minding other people's business, and in a hurry.

At this juncture, we congratulate the *New York State Journal of Medicine*, always the champion of medical autonomy, on an editorial in its October 2 issue in which it stresses the freedom of the medical profession from political alliances and entanglements. In this respect our profession, probably, comes closer to heeding the parting words of Washington than does any similar organization in the country, if not, indeed in the known world. This same editorial reaffirms the official commitment of the Medical Society of the State of New York to the proposition of voluntary medical-expense indemnity insurance.

A profession that goes so deeply into the lives and welfare of all the people can have no political affiliations; like the Red Cross, its functions are universal and above party considerations. Its very indispensability, however, to the Nation as a whole makes its activities and its ministrations a matter of concern to all people and all parties. If it cannot itself make its benefits universally available, then the attempt is bound to be made from without, and not well or wisely.

The scientific and the humane achievements of medicine have kept pace with the developments in other branches of human activity; its sociologic and economic aspects have been maturing more slowly, although they are making progress with the added desideratum of a sure footing. In Massachusetts, with the Blue Cross, the Blue Shield and now the Blue Triangle available, we are keeping well in the front of this economic progress, and ask only

THE TUMULT AND THE SHOUTING

REGULARLY every four years, in our democracy, come famine or plenty, health or pestilence, prosperity or depression, peace or war, a certain not too imposing percentage of the electorate goes to the polls; there it exercises its constitutional privilege of selecting from its nominated peers those who will arbitrate the destinies of the Nation for another forty-eight months.

Whether the choice of the voters at this regularly ordained and politically hallowed period of emotional instability is to turn the rascals out or to put the rascals in, is almost entirely a matter of the point of view, since for every vice there must be a versa. Fortunately the organized medical pro-

felt fairly sure of the situation from the previous examinations.

DR. SNIFFEN: In the absence of one kidney, does the pelvis on the other side enlarge or is it the parenchyma alone?

DR. BARNEY: More the parenchyma than the pelvis, unless there is some obstruction in the ureter, of which I see no indication in this film.

DR. SNIFFEN: Dr. Smith, you operated on this man, would you like to tell us your findings?

DR. GEORGE G. SMITH: This patient was in perfectly good health except for recurring attacks of hematuria that were due to a papillary tumor, which had recurred always in the same place. This was in the region of the left ureteral orifice. His right kidney never troubled him and was adequately sustaining life. It seemed to me that the chief thing was to get rid of the tumor of the lower left ureter, which was presumably an implant from the original papilloma of the left kidney pelvis. He had had a tumor cut off with the resectoscope in that region fairly recently; on cystoscopy the whole region of the left ureteral orifice was elevated and looked a little peculiar. I could feel nothing by bimanual examination, but it seemed to me that he should have the stump of the ureter and the adjacent bladder wall removed. That was done. The ureter was quite long, but I was able to free it to the upper end, which was well above the pelvic brim. The ureter was filled with thin purulent fluid. It was taken out without being opened, and the bladder wall was excised by an oval incision, which I think went entirely outside the indurated area. That was sewed up, and the bladder drained

by a catheter through the anterior bladder wall. The patient made an uneventful convalescence except that it took him longer to heal than we had hoped. He left the hospital on the eighteenth postoperative day.

I saw the patient yesterday, — about two months after discharge, — and he was in excellent health. The urine was infected, but he had not been on urinary antiseptics lately.

CLINICAL DIAGNOSIS

Papillary carcinoma of left ureter.

DR. BARNEY'S DIAGNOSIS

Neoplasm of left ureter, secondary to neoplasm of left renal pelvis.

ANATOMICAL DIAGNOSIS

Carcinoma (Grade IIB) of left ureter.

PATHOLOGICAL DISCUSSION

DR. SNIFFEN: Dr. Smith removed a disk of bladder about 3 cm. in diameter. In the center was the ureteral orifice and from it arose about 18 cm. of ureter. The ureter was dilated to three or four times its normal size and contained pus. In the ureter, about 1 cm. above the vesical orifice, was a tumor measuring approximately 1 cm. in diameter that completely obstructed the lumen. Several centimeters above it there were two other small tumors. Microscopic sections showed an infiltrating carcinoma of moderate malignancy. The neoplastic cells had spread to the neighboring lymphatics but not to the resected edge of the bladder.

MASSACHUSETTS MEDICAL SOCIETY

Although the Blue Shield is operating smoothly in the vast majority of cases, it is no different from any other undertaking, in that a few misunderstandings are bound to arise. In every such instance so far, it was the lack of information that caused the trouble.

Many participating physicians do not realize that the Blue Shield is, in effect, under separate contract with subscribers whose incomes are less than \$2500 for families and \$2000 for individuals. These "under-income" or "unlimited" subscribers, as they are called, are entitled to the benefits of their membership without any additional charge by participating physicians.

In a few cases, the failure on the part of the physician to determine whether or not a patient is a Blue Shield member has led to the following type of misunderstanding: A patient arranges with a surgeon for an operation at an agreed fee. Later, when he is well, the patient informs the surgeon for the first time that he is a Blue Shield subscriber and that he is entitled to unlimited service because of his low-income status. The surgeon is then obliged to accept the Blue Shield payment, which may or may not be as much as the agreed fee.

Although the subscribers' contract technically protects the physician in cases of this kind by specifically requiring the subscriber to identify himself as a Blue Shield member at the time arrangements are made for the operation, very poor public relations result when the physician bills the under-income subscriber for an additional charge. Participating physicians have agreed as a matter of principle that under-income subscribers should not have to pay extra charges for surgery and aftercare in the hospital.

It should be remembered, however, that the physician continues to charge his regular fee to those subscribers whose incomes are larger than the amounts stated above, and thus may quite properly

bill the over-income subscriber for the amount, if any, that his fee exceeds the Blue Shield payment.

A great deal of confusion could be avoided and public relations could be immeasurably benefited if the participating physician would simply ask each patient the following two questions: Are you a Blue Shield subscriber? If so, what is your income status? The physician would not then be working in the dark, and the arrangements concerning the fee could be made with complete understanding.

DEATHS

JOHNSON — David J. Johnson, M.D., of Boston, died October 7. He was in his seventy-second year.

Dr. Johnson received his degree from Harvard Medical School in 1897. He was a member of the American Medical Association.

His widow survives.

REEVES — Marcellus Reeves, M.D., of Boston, died October 15. He was in his eighty-second year.

Dr. Reeves received his degree from Harvard Medical School in 1890. He was a member of the American Medical Association.

His widow survives.

COMMENT

Anterior poliomyelitis continued high as compared with the seven-year median for the month of September, but at a figure far below that of epidemic years.

Diphtheria continued at too high a level. Only once since 1936 has September shown more cases. It is obvious that more children must be immunized.

Bacillary dysentery ran rather high during September — higher than during any previous month this year. Moreover, this figure has been exceeded only three times by the September figures of the last eleven years.

GEOGRAPHICAL DISTRIBUTION OF CERTAIN DISEASES

Anterior poliomyelitis was reported from Agawam, 1; Arlington, 1; Belmont, 1; Boston, 5; Boylston, 1; Braintree, 1; Brookline, 5; Cambridge, 2; Cheshire, 1; Chicopee, 7; Dalton, 2; Danvers, 1; Deerfield, 1; East Longmeadow, 1;

for freedom from bungling interference by any party.

The tumult and the shouting of an election year will soon die away; may it leave in high political places, as well as in the less conspicuous ranks of medical practice, the same ancient sacrifice of "a humble and a contrite heart"!

SYNTHETIC QUININE

THE sensational medical history of cinchona and its best-known alkaloid quinine¹ is being continued in our own time by the sealing off of the foremost natural source of cinchona bark when the Netherlands East Indies were seized by the Japanese early in the present war and by a great scientific achievement—the synthetic production of quinine.

The first event can be remedied by the passage of time and the successful outcome of the war. The second event can best be appreciated by reading the scholarly paper of Haggis¹ entitled "Fundamental Errors in the Early History of Cinchona." This account illustrates the extent by which the discovery and application of a remedial plant can be obscured by the past, and the painstaking labors necessary to unravel fact from fiction. Coincident with the increasing need of quinine for the treatment of malaria and the use of quinidine, another alkaloid of the cinchona bark, for cardiac treatment, the cinchona-bark industry grew. The patience and skill acquired by the Dutch in co-ordinating horticultural practice, soil science, chemistry and forest succession for the production of cinchona bark² are reflected in figures given by Taylor,³ who states that before the present war the world consumption of quinine was 722 tons annually and that before the invasion of Java, in the year 1941, the annual production was 1017 tons. In contrast to the centuries needed for the production of quinine by natural methods, the efforts of two chemists, Woodward and Doering,^{4, 5} over a period of fourteen months, have culminated in the synthetic production of quinine.

Much of the publicity attendant to this achievement gave the unfortunate impression that syn-

thetic quinine is now available and will relieve the need for other antimalarial drugs by the armed forces and that quinine is the most effective drug for prophylaxis and the production of radical cures. As a matter of fact, synthetic quinine is a scientific curiosity and is still far from being on a practical production schedule. Furthermore, the effectiveness of quinine as an antimalarial drug is far from 100 per cent. Quinine used prophylactically does not prevent infection, although it does suppress the development of clinical malaria. In treatment, an authoritative report by the League of Nations⁶ states:

The treatment of primary *P. vivax* and *P. malariae* infections with quinine in the usual doses [1 gm. daily] is followed by relapses in a proportion of individuals which may be as high as 50 per cent. . . . On the fully-developed gametocytes of *P. falciparum*, quinine has only a slight action.

An additional factor influencing the need for quinine is a recent report by the Board for the Coordination of Malarial Studies of the National Research Council,⁷ which claims that quinacrine (atabrine), when administered in proper dosages, produces results in the routine suppression and treatment of malaria that are comparable to those obtainable by the use of quinine or totaquine, one of the less highly purified derivatives of cinchona bark. In fact, the board stated: "There is convincing evidence that quinacrine not only suppresses the clinical symptoms of falciparum malaria but also cures this malignant form. The evidence of a similar curative effect of quinine is not conclusive." Unfortunately, relapses of vivax malaria are not prevented by quinacrine or quinine when a course of treatment is terminated.

All in all, it seems unlikely that the ingenuity of industrial chemists will be invoked to develop a means for the commercial production of synthetic quinine, as it was for the manufacture of penicillin. This in no way detracts from the brilliant experiments of Woodward and Doering. In fact, their method for the synthesis of quinine may eventually lead to the long-sought ideal—an antimalarial drug that is 100 per cent effective. Until such time, adequate amounts of the known antimalarial drugs and skill in their administration comprise the most potent weapon in the battle against malaria.

PENICILLIN IN SULFONAMIDE-RESISTANT GONORRHEA*

A Review of 200 Cases

LIEUTENANT COMMANDER N. S. SCARCELLO (MC), U.S.N.R.

ST. ALBANS, LONG ISLAND, NEW YORK

ALTHOUGH penicillin was discovered in 1929 by H. Fleming,¹ its use in clinical work did not take place until 1940. In that year a group of Oxford investigators² published a paper entitled "Penicillin: A Chemotherapeutic Agent." This was followed in 1941 with another report on the practical use of penicillin.³ From then on, reports of the miraculous effect of the drug have been increasing daily. Limited supplies were insufficient for all investigators, and since penicillin was being manufactured under government supervision, it was reserved chiefly for military use.

It was early recognized that penicillin has a definite place in sulfonamide-resistant cases.^{4, 5} This was proved by tests with sulfonamide-resistant organisms and by treating sulfonamide-fast cases of gonorrhea.⁶

Permission to use penicillin at the United States Naval Hospital in St. Albans, Long Island, was given in July, 1943, by the Bureau of Medicine and Surgery. To affect the maximum utilization of the limited quantities available, it was directed that it be used in cases of sulfonamide-resistant gonorrhea. These were cases that had failed to respond to two courses of sulfonamides, each course consisting of at least 20 gm. of the drug.

PHARMACOLOGY

Penicillin is produced from the mold *Penicillium notatum*. It is supplied in sterile ampoules as a sodium salt for clinical use and appears as a yellow or light-brown amorphous powder. It is readily soluble in water and in saline and glucose solutions, and is subject to deterioration if exposed to high temperatures or even to room temperatures for an extended period of time. It is stable to light, but must be kept stored at a temperature

below 5°C. — whether in powder form or in solution. It is readily absorbed when given by the intramuscular route and more slowly when given subcutaneously, and is rapidly excreted through the urinary tract,⁷ a large part of the injected drug being lost within a few hours. This must be kept in mind to obtain the best results and to maintain a sufficient concentration of the drug within the blood stream. It must be given in sufficient doses and at frequent regular intervals, as may be required for the specific infection under treatment.

Although penicillin has a powerful bacteriostatic action,^{8, 9} it has been found to have some bactericidal action as well. It is remarkably effective in the treatment of infections produced by *Staphylococcus aureus*, pneumococci and hemolytic streptococci. In general, penicillin is not effective against gram-negative organisms. Exceptions to this rule are the gonococci and meningococci. The gonococci, especially those in the sulfonamide-resistant group, appear to be remarkably susceptible.

Penicillin has so far proved to be nontoxic.¹⁰⁻¹²

METHOD OF STUDY

This paper is a review of 200 cases of sulfonamide-resistant gonorrhea treated with penicillin, in the majority of which a sulfonamide drug had been given for at least two weeks, representing a total of 40 gm. The periods of sulfonamide therapy were as follows: in 6 cases, at least one week; in 44 cases, two weeks; in 35 cases, three weeks; in 34 cases, four weeks; in 18 cases, five weeks; in 23 cases, six weeks; in 23 cases, seven weeks; in 6 cases, eight weeks; in 4 cases, nine weeks; and in 7 cases, ten weeks.

On entry all the patients had a positive urethral or prostatic smear or culture, or both. One hundred and twenty-nine patients had a marked urethral discharge, 16 a moderate discharge, 46 a slight discharge, and 9 either a "morning tear" or a positive prostatic culture.

Using the two-glass test, the second sample was clear in approximately 75 per cent of the pa-

NOTICES

AMERICAN FEDERATION FOR CLINICAL RESEARCH

An all-day meeting of the Eastern Section of the American Federation for Clinical Research is being planned for December 9. Investigators desiring to read papers on clinical research should submit an abstract of not over 200 words to Dr. Orville Bailey, Harvard Medical School, 25 Shattuck Street, Boston 15, before November 15. The meeting will be held in Boston and will be open to members of the medical profession.

POSTGRADUATE CLINICS IN DERMATOLOGY AND SYPHILIS

Owing to requests for postgraduate work in dermatology and syphilology, the Department of Cutaneous Diseases and Syphilis of the Boston City Hospital will conduct weekly clinics for instruction in the diagnosis and treatment of cutaneous diseases and syphilis. All physicians are invited.

Meetings will be held in the Dowling Amphitheatre on Fridays at 10:50 a.m. during the academic year. The first meeting was held October 6, when a symposium on psoriasis was conducted.

NEW ENGLAND HOSPITAL FOR WOMEN AND CHILDREN

The monthly clinical conference and meeting of the staff of the New England Hospital for Women and Children will be held on Thursday, November 2, in the classroom of the Nurses' Residence, at 7:15 p.m. Dr. Maurice Fremont Smith will speak on the subject "The Use and Misuse of Hormone Therapy." Dr. Anne Hopkins will be chairman.

JOSEPH H. PRATT DIAGNOSTIC HOSPITAL

Bennet Street, Boston
Lecture Hall, 9-10 a.m.

MEDICAL CONFERENCE PROGRAM

Wednesday, November 1 — Penicillin in Venereal Disease Dr. Oscar F. Cox.

Friday, November 3 — The Effect of Testosterone Compounds in Hyperthyroidism. Dr. Edward C. Reifstein Jr.

Wednesday, November 8 — Modern Anesthesia. Dr. Frank W. Marvin.

Friday, November 10 — Review of Electroencephalograms Made on Pratt Diagnostic Hospital Cases. Dr. John A. Abbott.

Tuesday, November 14 — Newer Diuretics Dr. Werner Lipschitz.

Wednesday, November 15 — Present-Day Treatment of Hypertension. Dr. David Ayman.

Friday, November 17 — Recent Advances in Cardiology Dr. Samuel Levine.

Wednesday, November 22 — Arterial Insufficiency in the Lower Extremities. Dr. John Homans.

Friday, November 24 — Diagnosis of Uterine Cancer by Vaginal Smear. Dr. Joe Vincent Meigs.

Wednesday, November 29 — Signs and Symptoms of Nutritional Disturbances. Motion picture film shown through the courtesy of E. R. Squibb & Sons.

On Monday mornings clinics will be given by Dr. Samuel Proger. On Saturday mornings clinics will be given by Dr. William Dameshek.

On Tuesday and Thursday mornings Dr. S. J. Thannhauser will give medical clinics on hospital cases.

SOCIETY MEETINGS AND CONFERENCES

CALENDAR OF BOSTON DISTRICT FOR THE WEEK BEGINNING THURSDAY, NOVEMBER 2

THURSDAY, NOVEMBER 2

7:15 p.m. The Use and Misuse of Hormone Therapy Dr. Maurice Fremont-Smith New England Hospital for Women and Children

FRIDAY, NOVEMBER 3

10:50 a.m. Postgraduate clinic in dermatology and syphilis Dowling Amphitheatre, Boston City Hospital

SATURDAY, NOVEMBER 4

*10:00 a.m.-12:00 m. Medical staff rounds Peter Bent Brigham Hospital

MONDAY, NOVEMBER 6

12:00 m.-1:00 p.m. Clinicopathological conference Peter Bent Brigham Hospital

TUESDAY, NOVEMBER 7

*12:15-1:15 p.m. Clinicoroentgenological conference Peter Bent Brigham Hospital

WEDNESDAY, NOVEMBER 8

*12:00 m. Clinicopathological conference Children's Hospital.
7:15 p.m. Graduate seminar in pediatrics Children's Medical Service, Massachusetts General Hospital, Amphitheatre 3A

*Open to the medical profession.

10,000-Unit Group

Case 77. This case was complicated by a prostatic abscess moderate retention. The patient had received sulfonamide treatment over a period of months, along with irrigations and instillations. The first course of penicillin cleared acute symptoms and retention almost immediately. Discharge recurred 1 week later, and a second course (30,000 units) was given, with excellent results.

Case 86. The patient had received sulfonamide therapy for 3 weeks. Following the first course of penicillin, the discharge persisted and the cultures and smears remained positive. A second course (25,000 units) was given 2 weeks later, with no apparent improvement. Two weeks later a third course (50,000 units) was given with excellent results.

Case 144. The patient, a Negro, had received sulfonamide therapy for 3 weeks. The discharge persisted following the first course of penicillin, but cleared up immediately when a second course (25,000 units) was given 2 weeks later. The patient went to O.L., and on return had a discharge. A third course (50,000 units) brought a good response.

Case 165. The patient had received sulfonamide therapy for 5 weeks. The discharge persisted following the first course of penicillin, but after a second course 6 days later it cleared and the patient improved.

Case 176. The patient had received sulfonamide therapy for 5 weeks. He responded poorly to the first course of penicillin, the discharge continuing and the cultures remaining positive. A second course (25,000 units) produced excellent results.

30,000-Unit Group

Case 69. The patient had received sulfonamide therapy for 3 weeks. The discharge persisted following the first course of penicillin, and two weeks later an acute epididymitis developed. Four weeks after the first course, a second course (70,000 units) was given, with good results.

Case 74. The patient had received sulfonamide therapy for 10 weeks. The discharge persisted following the first course of penicillin. A second course was given 4 days later and had no effect, and a third was given 4 days after the second, with good results.

Case 80. The patient had received sulfonamide therapy for 10 weeks. The first course of penicillin failed to stop the discharge, and the cultures were positive, so that a second course (30,000 units) was given, with good results.

Case 171. The patient, who entered the hospital with a severe acute epididymitis, had received sulfonamide therapy for 2 weeks. He did not respond well to the first course of penicillin, and a second course (30,000 units) was given 8 days later, but the smears remained positive. A third course (25,000 units) was given 2 weeks later. Following this the cultures became negative, but the discharge recurred, and a fourth course (50,000 units) was given, with good results.

50,000-Unit Group

Case 99. The patient, a Negro, had received sulfonamide therapy for 2 weeks. The first course of penicillin resulted in negative cultures and smears, and a second course (50,000 units) 2 weeks later stopped a recurrent discharge.

Case 101. The patient had received sulfonamide therapy for 2 weeks. A second course (40,000 units) was necessary to control the profuse discharge that the first course of penicillin had failed to control.

Case 110. The patient had received sulfonamide therapy for 3 weeks. There was a recurrence of the discharge 1 week after the first course of penicillin, so that a second course (25,000 units) was given, with a good effect.

Case 123. The patient had received sulfonamide therapy for 10 days. Owing to a persistent slight discharge following the first course, a second course (25,000 units) of penicillin was administered and produced a clinical cure.

Case 135. The patient had received sulfonamide therapy for 2 weeks. The first course of penicillin produced good results, except that the patient developed a "morning drop." A second course (50,000 units) was given, with immediate good results.

Case 143. The patient had received sulfonamide therapy for 6 weeks. The cultures remained positive after the first course of penicillin. A second course (30,000 units) resulted in clinical cure.

Case 184. The patient had received sulfonamide therapy for 12 days. The discharge recurred 4 days after the first course of penicillin, and the cultures remained positive. A second course (30,000 units) given 5 days later was followed by good results.

30,000-Unit Group

Case 112. The patient, a Negro, had already been discharged clinically cured after a course of 60,000 units of penicillin. On readmission he was given sulfonamide therapy followed by 30,000 units of penicillin, with poor results. One week later a second course (25,000 units) was given, but positive cultures were obtained only after a third course (30,000 units).

Case 141. The patient, a Negro, had received sulfonamide therapy for 2 weeks. Although cultures became negative after the first course of penicillin, the discharge kept recurring, so that a second course (35,000 units) was given 3 weeks later. A third course (100,000 units) 1 week later produced good results.

COMPLICATIONS

Twenty-nine patients had complications on entry or developed them while in the hospital.

There were 3 patients with gonorrheal arthritis who received penicillin, and all had an immediate good response.

There were 4 cases of prostatic abscess, and all the patients showed an immediate good response to penicillin therapy.

Seventeen patients had an acute epididymitis on entry, and 5 developed epididymitis following penicillin. Penicillin had little or no apparent effect on this condition. All the patients required symptomatic treatment and bed rest, and the course of the epididymitis was not shortened by penicillin.

DISCUSSION

Penicillin has so far lived up to the predictions made for it, and has a definite place in the treatment of cases of sulfonamide-resistant gonorrhea.

No toxic reactions were noted in this series.

The Negro patients did not respond well to the drug, and approximately half of them required a repeat course.

Penicillin had little noticeable effect on the cases complicated by epididymitis, although immediate good results were obtained in the cases with gonorrheal arthritis and prostatic abscess.

The patients receiving initial courses of large dosage (100,000 units) required fewer repeat courses than those who were given smaller dosages and such a dosage should be used whenever possible.

Sulfonamide therapy should be continued as long as possible to keep the infection localized, even though clinical improvement is not noted. Irrigations and instillations, the cause of the majority of complications, should be avoided whenever possible.

The question of chancre should always be kept in mind, since some observers have found that

tients, which indicated that the infection, although not cured by the sulfonamide therapy, had been confined to the anterior urethra.

On entry, smears were taken in all cases and a two-glass test was done. While waiting for penicillin, and if there were no contraindications, the patients were given either sulfathiazole or sulfadiazine.

The penicillin was dissolved in sterile distilled water, 20 cc. of water to each 100,000 units. All the medication was given intramuscularly, with the buttocks being the site of choice and the injections alternated between them. At present, the patients receive five injections of 4 cc. (20,000 units) each at two-hour or three-hour intervals, with restriction of fluid, for a total of 100,000 units, this so-called "course" having been found to give the best results. Although there was an occasional complaint of soreness, this was no more than was to be expected with intramuscular injections, and was probably due to the giving of repeated injections in the same area. No complications followed this mode of administering the drug.

CLINICAL RESULTS

As is shown in Table 1, the total dosages of the initial courses varied, owing to the trial of different amounts. There were 27 cases (14 per cent) requiring two or more courses of penicillin. There were no failures, and all the cases cleared up after the second

TABLE 1. *Amounts of Penicillin Administered.*

NO OF CASES	DOSAGE OF INITIAL COURSE units	CASES REQUIRING REPEAT COURSES*	
		NO.	PERCENTAGE
18	150,000	1	6
15	120,000	0	0
63	100,000	8	13
31	75,000	5	16
15	60,000	4	27
56	50,000	7	13
2	30,000	2	100

*Repeat courses were given to patients who continued to have a discharge or a positive prostatic culture following the first course of penicillin.

or third course. The criterion followed for a so-called "clinical cure" was two negative prostatic cultures and smears. This regime was carried out so far as possible with due consideration to military exigencies and to the jeopardizing of the patient's condition.

More than 80 per cent of the patients had no visible urethral discharge twenty-four hours after the first course, but a few had a mucoid discharge for three or four days.

As shown by Table 1, the percentage of cases requiring repeat courses was less when large initial courses were given. Ninety-six patients received 100,000 or more units in the initial course, and only 9 of them (9 per cent) required repeat courses. There were 104 patients who received 80,000 or

less units, 18 of whom (17 per cent) required repeat courses.

The average number of hospital days in the series was reduced to approximately a third of that usually to be expected.

ANALYSIS OF REPEAT-COURSE CASES

In the following section, the cases requiring repeat courses are analyzed in brief reports, which are divided according to the number of units of penicillin given in the initial course.

Of the cases requiring repeat courses, 18 cleared up following the first repeat course, 7 required two repeat courses, and 2 needed three repeat courses.

150,000-Unit Group

Case 79. The patient had received sulfonamide therapy for 4 weeks, with no apparent clinical improvement. He did not respond well to the first course of penicillin. Four days after its administration, he developed an acute epididymitis, which was treated symptomatically. Discharge still persisted, so that a second course of 60,000 units was given 4 weeks after the first one, and the patient subsequently improved.

100,000-Unit Group

Case 68. The patient, a Negro, had previously received sulfonamide therapy for 5 weeks. Although the discharge cleared following the first course of penicillin, he continued to have a positive prostatic culture, so that a second course was given 3 weeks after the first, following which cultures became negative.

Case 78. The patient had received sulfonamide therapy for 6 weeks. Following the first course of penicillin (60,000 units), prostatic cultures remained positive, and a repeat course was given 10 days later. Cultures then became negative.

Case 82. The patient, a Negro, had received sulfonamide therapy for 9 weeks. Positive cultures persisted following the first course of penicillin, although clinically he appeared cured, with no discharge and a clear urine. Two weeks after the first course, a second one of 60,000 units was given, followed by a third of 100,000 units 2 weeks later, after which negative cultures were obtained.

Case 87. The patient, a Negro, had received sulfonamide therapy for 9 weeks. After the first course of penicillin the discharge ceased and the urine cleared, but the prostatic smears remained positive, and 10 days later the discharge recurred. A second course of 50,000 units was given, following which the discharge ceased and the cultures became negative.

Case 89. The patient had received sulfonamide therapy for 7 weeks. After the first course of penicillin the discharge, although slight, persisted for 1 week. A second course of 25,000 units was given and the patient became clinically cured.

Case 114. The patient had received sulfonamide therapy for 5 weeks. The discharge, although diminished, persisted after the first course of penicillin, but cleared up immediately following the administration of a second course of 25,000 units.

Case 142. The patient had received sulfonamide therapy for 7 weeks. On entry his condition was complicated by an acute epididymitis. The discharge persisted after the first course of penicillin and the cultures remained positive. A second course (25,000 units) was given, with no improvement 2 weeks later. A third course was given 1 week later, with no clinical improvement. One week later a fourth course of 50,000 units was given, and the smears and cultures became negative.

Case 167. The patient had received sulfonamide therapy for 4 weeks. A slight discharge persisted following the first course, and a second course of 25,000 units was given, with excellent results.

10,000-Unit Group

Case 77. This case was complicated by a prostatic abscess moderate retention. The patient had received sulfonamide treatment over a period of months, along with irrigation and instillations. The first course of penicillin cleared acute symptoms and retention almost immediately. Discharge recurred 1 week later, and a second course (30,000 units) was given, with excellent results.

Case 86. The patient had received sulfonamide therapy for 3 weeks. Following the first course of penicillin, the discharge persisted and the cultures and smears remained positive. A second course (25,000 units) was given 2 weeks later, with no apparent improvement. Two weeks later a third course (50,000 units) was given with excellent results.

Case 144. The patient, a Negro, had received sulfonamide therapy for 3 weeks. The discharge persisted following the first course of penicillin, but cleared up immediately when a second course (50,000 units) was given 2 weeks later. The patient went to O.L., and on return had a discharge. A third course (50,000 units) brought a good response.

Case 165. The patient had received sulfonamide therapy for 5 weeks. The discharge persisted following the first course of penicillin, but after a second course 6 days later it cleared and the patient improved.

Case 176. The patient had received sulfonamide therapy for 5 weeks. He responded poorly to the first course of penicillin, the discharge continuing and the cultures remaining positive. A second course (25,000 units) produced excellent results.

30,000-Unit Group

Case 69. The patient had received sulfonamide therapy for 3 weeks. The discharge persisted following the first course of penicillin, and two weeks later an acute epididymitis developed. Four weeks after the first course, a second course (70,000 units) was given, with good results.

Case 74. The patient had received sulfonamide therapy for 10 weeks. The discharge persisted following the first course of penicillin. A second course was given 4 days later and had no effect, and a third was given 4 days after the second, with good results.

Case 80. The patient had received sulfonamide therapy for 10 weeks. The first course of penicillin failed to stop the discharge, and the cultures were positive, so that a second course (30,000 units) was given, with good results.

Case 171. The patient, who entered the hospital with a severe acute epididymitis, had received sulfonamide therapy for 2 weeks. He did not respond well to the first course of penicillin, and a second course (30,000 units) was given 8 days later, but the smears remained positive. A third course (25,000 units) was given 2 weeks later. Following this the cultures became negative, but the discharge recurred, and a fourth course (50,000 units) was given, with good results.

50,000-Unit Group

Case 99. The patient, a Negro, had received sulfonamide therapy for 2 weeks. The first course of penicillin resulted in negative cultures and smears, and a second course (50,000 units) 2 weeks later stopped a recurrent discharge.

Case 101. The patient had received sulfonamide therapy for 2 weeks. A second course (40,000 units) was necessary to control the profuse discharge that the first course of penicillin had failed to control.

Case 110. The patient had received sulfonamide therapy for 5 weeks. There was a recurrence of the discharge 1 week after the first course of penicillin, so that a second course (25,000 units) was given, with a good effect.

Case 123. The patient had received sulfonamide therapy for 10 days. Owing to a persistent slight discharge following the first course, a second course (25,000 units) of penicillin was administered and produced a clinical cure.

Case 135. The patient had received sulfonamide therapy for 2 weeks. The first course of penicillin produced good results, except that the patient developed a "morning drop." A second course (50,000 units) was given, with immediate good results.

Case 143. The patient had received sulfonamide therapy for 6 weeks. The cultures remained positive after the first course of penicillin. A second course (30,000 units) resulted in clinical cure.

Case 184. The patient had received sulfonamide therapy for 12 days. The discharge recurred 4 days after the first course of penicillin, and the cultures remained positive. A second course (30,000 units) given 5 days later was followed by good results.

30,000-Unit Group

Case 112. The patient, a Negro, had already been discharged clinically cured after a course of 60,000 units of penicillin. On readmission he was given sulfonamide therapy followed by 30,000 units of penicillin, with poor results. One week later a second course (25,000 units) was given, but positive cultures were obtained only after a third course (30,000 units).

Case 141. The patient, a Negro, had received sulfonamide therapy for 2 weeks. Although cultures became negative after the first course of penicillin, the discharge kept recurring, so that a second course (35,000 units) was given 3 weeks later. A third course (100,000 units) 1 week later produced good results.

COMPLICATIONS

Twenty-nine patients had complications on entry or developed them while in the hospital.

There were 3 patients with gonorrheal arthritis who received penicillin, and all had an immediate good response.

There were 4 cases of prostatic abscess, and all the patients showed an immediate good response to penicillin therapy.

Seventeen patients had an acute epididymitis on entry, and 5 developed epididymitis following penicillin. Penicillin had little or no apparent effect on this condition. All the patients required symptomatic treatment and bed rest, and the course of the epididymitis was not shortened by penicillin.

DISCUSSION

Penicillin has so far lived up to the predictions made for it, and has a definite place in the treatment of cases of sulfonamide-resistant gonorrhea.

No toxic reactions were noted in this series.

The Negro patients did not respond well to the drug, and approximately half of them required a repeat course.

Penicillin had little noticeable effect on the cases complicated by epididymitis, although immediate good results were obtained in the cases with gonorrheal arthritis and prostatic abscess.

The patients receiving initial courses of large dosage (100,000 units) required fewer repeat courses than those who were given smaller dosages and such a dosage should be used whenever possible.

Sulfonamide therapy should be continued as long as possible to keep the infection localized, even though clinical improvement is not noted. Irrigations and instillations, the cause of the majority of complications, should be avoided whenever possible.

The question of chancre should always be kept in mind, since some observers have found that

to return these patients to duty in one third of the time previously required.

Penicillin has definitely proved its worth in the treatment of such cases. It has made it possible

MAJOR ROBERT W. HYDE, M.C., A.U.S., AND STAFF SERGEANT RODERICK M. CHISHOLM, A.U.S.

wherein 60,000 consecutive selectees were examined. A great diversity of population density is represented, at its greatest in Boston and least in the areas of Cape Cod and the farming areas to the north and south of Boston. Most of the area studied is highly industrialized, with a diversity of mills and factories, but significant sectors are devoted to farming and fishing. The age range of the selectees was from eighteen to forty-four, with most of them between twenty-one and thirty-eight. All social strata were represented, and the group may be said to form a representative cross section of the male population at large.

The people of the area represented a wide variety of nationalities. A few communities were of almost pure English stock, now in the sixth and seventh generation in this country; others, particularly in the dense areas, were of almost completely foreign parentage. The first extensive immigration after colonial times was that of the Irish in the middle of the nineteenth century. Since that time numerous Italians have moved into the commercial areas of Boston and other coastal towns. The Portuguese have moved into the fishing villages of Cape Cod and into Fall

Selectees from the eastern segment of Massachusetts within thirty-five miles of the coastline were examined at the Boston Armed Forces Induction Station. The period covered was the winter, spring and summer months of 1941 and 1942,

er and New Bedford, and Russian Jews into ton's commercial and residential districts. The test proportion of the Chinese arrived here a China within the last decade. Many of the groes came from the South during the depression he 1930's. The Chinese have settled in one the densest areas of Boston, and the Negroes a moderately dense area of that city. he psychiatric examination, described else- ere,¹ was necessarily brief. Mental deficiency determined by a team of psychologists. The

studies^{2,3} the extent to which these factors are relevant to the incidence of mental disorders has been outlined. It was therefore possible to isolate the psychiatric differences that may have been due to racial or national factors from those that were apparently due to economic status or to population density.

RESULTS

Table 1 shows the variation of comparative rejection rates for the major mental disorders found

ost important causes of psychiatric rejection are mental deficiency, psychopathic personality, chronic alcoholism, psychoneurosis and psychoses. is with these major disorders that this study concerned.

The number from each community disqualified or each of these mental defects was ascertained. selectees are grouped in specific communities by selective Service boards. Each board represents either a city ward in a large city, part of a small city, a large town or several adjacent small towns. Although these artificial community groupings are probably not the best obtainable, they correspond to fairly distinct community entities.

In the consideration of race and nationalities, only those communities were included wherein the majority of the selectees were of the same general nativity. Our findings are doubtless influenced to some extent by the fact that a minority of different mixed nationalities is represented in each community. One advantage of a community consideration, however, is the fact that persons of a given nationality in an immigrant community retain more of the characteristics and habits of that nationality than do those who have scattered as a minority into American communities. The data concerning the Irish, Italian, Portuguese, Jews and Old Americans are derived from a community consideration. Those concerning the Negroes and Chinese are based on a consideration of Negro and Chinese selectees, irrespective of community groupings here, since none of the groupings represented are predominantly Chinese or Negro.

The population density and socioeconomic level of each community were estimated. In preceding

in selectees from the communities of different predominant nationalities. The average density and socioeconomic level of each group of communities of similar nationality are also noted so that corrections can be made for differences that may be traceable to these causes. Socioeconomic ratings vary from A (best) to F (poorest). The most outstanding figures are the exceptionally high rate of disorders among the Negroes and Chinese. This is especially noteworthy in view of the fact that the figures for these two groups are based on individuals and therefore are not distorted by minorities of other nationalities. The table also shows that there is an obvious parallelism between the total mental disorders and the population density and socioeconomic level of each community represented. This parallelism is so marked that the table cannot be considered to present a clear picture of racial or national differences as such. The significance of racial and national differences becomes evident only when one considers the distribution of different mental disorders within each national grouping.

The Irish communities show high rates of psychopathic personality and chronic alcoholism (Table 2). These communities are high in density — from 10,000 to 20,000 per square mile — and are of the lowest (E and F) desirability. This fact may account for their high rate of psychopathy. The rate for chronic alcoholism cannot be similarly explained, since the Chinese, who live in a community that is at least as dense and as undesirable economically as those of the Irish, show an absence of alcoholism. Studies of hospital admissions have confirmed the findings that the rate of alcoholism

treatment with penicillin obscures the detection of a chancre in its early stages.

There were 2 patients in this series who, although they had received 60,000 units of penicillin, had been suspected of having a chancre. One case was diagnosed by dark-field examination, but in the other it was necessary to wait for the blood to become serologically positive. In the latter, a dorsal slit showed a scarred area on the corona that was apparently a healed lesion.

There were apparently only 2 patients in this series who had previously had gonorrhea. This is misleading, owing to the fact that once men are returned to duty, they may be hospitalized in any part of the world, making a thorough follow-up impossible.

SUMMARY

Two hundred cases of sulfonamide-resistant gonorrhea treated with penicillin have been reviewed and the findings and results tabulated. There were no toxic reactions, and all the patients were able to return to duty.

Penicillin has definitely proved its worth in the treatment of such cases. It has made it possible

to return these patients to duty in one third of the time previously required.

STUDIES IN MEDICAL SOCIOLOGY

III. The Relation of Mental Disorders to Race and Nationality

MAJOR ROBERT W. HYDE, M.C., A.U.S., AND STAFF SERGEANT RODERICK M. CHISHOLM, A.U.S.

BOSTON

RACIAL and national differences in admission rates to mental hospitals have been frequently studied, but there has never been an extensive study of such differences in the rate of mental disorders found in the population at large. The examination of selectees for induction into the armed forces provides a clear picture of the mental disorders in a cross section of the population, since selectees present the most unselected male group obtainable. The present study, based on data derived from the psychiatric examinations at the Boston Armed Forces Induction Station, shows the variation in rates for the major psychiatric disorders in communities grouped according to predominant nationality. An attempt is made to explain on a cultural basis those disorders that appear clearly to be connected with the predominant races or nationalities studied.

METHODS OF STUDY

Selectees from the eastern segment of Massachusetts within thirty-five miles of the coastline were examined at the Boston Armed Forces Induction Station. The period covered was the winter, spring and summer months of 1941 and 1942,

wherein 60,000 consecutive selectees were examined. A great diversity of population density is represented, at its greatest in Boston and least in the areas of Cape Cod and the farming areas to the north and south of Boston. Most of the area studied is highly industrialized, with a diversity of mills and factories, but significant sectors are devoted to farming and fishing. The age range of the selectees was from eighteen to forty-four, with most of them between twenty-one and thirty-eight. All social strata were represented, and the group may be said to form a representative cross section of the male population at large.

The people of the area represented a wide variety of nationalities. A few communities were of almost pure English stock, now in the sixth and seventh generation in this country; others, particularly in the dense areas, were of almost completely foreign parentage. The first extensive immigration after colonial times was that of the Irish in the middle of the nineteenth century. Since that time numerous Italians have moved into the commercial areas of Boston and other coastal towns. The Portuguese have moved into the fishing villages of Cape Cod and into Fall

and population density. It is not known whether the Negroes are forced to live at a level lower than that of the other population of the same community. The exceptionally high rate of mental disorders among them cannot be explained merely on the basis of population density or socioeconomic level. The Negroes show the highest rate for

equally explained on the basis of the high socioeconomic level and intermediate population density of their communities.

DISCUSSION

Tables 1 through 8 indicate in general that, though density and economic level may be of major importance in the etiology of mental disorders, there are significant variations that can be explained only by reference to factors related to race or nationality. We shall attempt to show which differences are directly related to differences in density and economic level and which require reference to racial or national factors. In suggesting a cultural explanation of these variations, no attempt is made to minimize the importance of biology and heredity. Heredity and environment are so entwined that it is extremely difficult to weigh their relative importance. A community study of this sort, however, presents an excellent opportunity to note the significance of environmental factors. So little is known at the present time about the etiology of mental disorders that the best one can attempt to do is to suggest the ones that an adequate explanation ought to take.

It is assumed that the so-called "functional" mental disorders are manifestations of the emo-

tional stress and tension that result when the individual has been subjected to abnormal deprivations and frustrations. The most primitive outlets to stress are those of aggressiveness, belligerency, acquisitiveness, sexual freedom and other asocial conduct falling under the term "psychopathic personality." Chronic alcoholism is another primitive outlet, which may either be associated with aggressiveness or act as a substitute for it. When this type of outlet is blocked, the stress may manifest itself in another form. With cultural taboos against asocial conduct or alcoholism, stress may turn itself inward and the subject may then become psychoneurotic. Mental disorders thus depend partly on the acceptability of the outlet for stress.

Mental disorders also seem to depend upon the type of stress to which the individual is subjected. Aggressiveness follows on the frustration of elementary physical needs, but usually not frustration of more developed or "intellectual" needs. In the lowest economic level, where these higher-type needs have not had the opportunity to develop, the natural and accepted outlet to stress is psychopathy. In the more desirable communities where it is mainly the higher-type desires that are frustrated, the natural outlet is psychoneurosis. Indeed, as a rule it is only in the communities at the lowest point on the desirability scale, the F communities, that psychopathy prevails; one need only move up one step, to the E communities, to note a marked change in the pattern of mental disorders.

In addition to the frustrations and deprivations that are related directly to high population density and low socioeconomic level, there are further sources of stress to which most of the racial groups here considered are subject. When people are transplanted into a new and unfriendly environment, requiring different cultural standards and patterns of conduct, they are subject to varying difficulties of adaptation. Social and racial prejudice leads to inequality in the opportunities for jobs and housing, and suspicion and insults suffered at the hands of the dominant native population breed feelings of inferiority and resentment. When the prejudice is intense enough, the immigrants withdraw into segregated and isolated groups. Parents attempt to bring up their children according to the precepts of their Old World culture, at the same time that the children are attending American schools, speaking English and becoming Americans in appearance, habits and customs. The children are expected to adjust themselves to divergent cultures, and the resultant conflict tends to create both humiliation and disrespect for authority.

Numerous studies have shown that crime and delinquency rates are higher among the second generation than among the immigrant parents.⁷⁻⁹ Levy¹⁰ has attributed this to the conflict between

among the Irish is probably higher than those among other national groups for whom statistics are available.⁴ During World War I, the Irish

showed a significantly high rejection rate for so-called "alcoholic psychoses."⁵

Four Italian communities are represented. One of them is low in density, having from 1000 to 2000 persons per square mile, 1 is intermediate, and 2 are high, being over 20,000. The two densest communities are also of the lowest socioeconomic level (F). The least dense of the 4 communities has a desirability rating between D and E, and the other community has a C rating. The most noteworthy features of the Italian pattern are the high rate of mental deficiency and, as compared with the Irish, the relatively low rate of chronic alcoholism (Table 3). There is also a significant difference

between the Italians and the Irish in the incidence of psychopathy and psychoneurosis.

Four Portuguese communities are represented. Two are low in density (from 2000 to 5000), 1 is intermediate (from 5000 to 10,000), and 1 is moderately high (from 10,000 to 20,000). They range in desirability from C to E, inclusive. In contrast to the Italian pattern, psychoneurosis is the primary cause of psychiatric rejection and psychopathy is less important (Table 4). The Portuguese rate of mental deficiency is comparable to that of

the Italians. The incidence of mental deficiency among the Portuguese and Italians cannot be ex-

plained wholly in terms of economic level or population density.

There are three Jewish communities, 1 in the highest density (over 20,000) and 2 intermediate (from 10,000 to 20,000); 1 is at desirability level D 1 between D and E and 1 at E. The most interesting findings are the high rate of psychoneurosis and the low rate of alcoholism (Table 5). In United States draft statistics for the last war, the Jews were highest in psychoneurosis and among the lowest in "alcoholic psychosis,"⁵ and peacetime hospital

statistics confirm these findings.⁶ Population density and socioeconomic level do not provide a satisfactory explanation of this pattern of mental disorders.

Boston's Chinatown is at the lowest desirability level and has a population density of over 20,000 per square mile. Although some of the Chinese registrants live elsewhere, the majority considered do live in Chinatown. The most interesting findings in Table 6 are the disproportionately high rate of mental deficiency, the low rate of psychopathy and the absence of alcoholism. This pattern, which

TABLE 6. *Mental Disorders Among Chinese*

cannot be explained on the basis of community desirability or population density, provides striking evidence of the significance of racial or national factors.

The term "mental deficiency" as applied to the Chinese is somewhat unfortunate, since the majority of the Chinese who are called mentally deficient are probably not feeble-minded in the ordinary usage of the term, but, as will be explained, are under so severe a cultural handicap that they are judged unable to absorb military training.

No single community represented among Selective Service boards is predominantly Negro. Although most of the Negroes live in dense communities of the lowest socioeconomic level, it is impossible to make proper corrections for socioeconomic

essions of immigrant stress; they suffer from adjustment resulting from a rural-urban shift, larger numbers come from rural areas in China; are deprived of many outlets by the presence of their families in China and by the shortage of Chinese women here. Yet the rate for psychopathy among them is comparatively low. This finding tends to indicate clearly the significance of racial factors in the etiology of mental disorders. Whether, in this case, the factors are biologic we cannot say, but it is clear that the culture of the Chinese has hindered both psychopathy and alcoholism unacceptable as outlets to stress. This rejection of violence is evident in the Chinese religious philosophy, which, like the religion of the Jews, serves to instill a deep respect for the law of the country. Psychoneurosis remains as the primary outlet for stress of the Chinese. Had those rejected for mental deficiency been able to express themselves more fully, psychoneurosis would probably have been used even oftener. (This error is not involved in the psychopathic or alcoholic groups, for adequate social-service records are available.)

The Negroes have the highest rate for both psychoneurosis and psychopathy. One reason for this may be that the Negroes in this study come from communities of varying densities and economic levels. A further and possibly more significant factor is the intensity and severity of the stress to which many of the Negroes are subjected. Aggressiveness is a natural reaction to physical stress, and when the stress is severe enough the individual is so completely oppressed that any impulse to aggressiveness is itself frustrated. When this happens the individual seldom hopes to overcome oppression and resigns himself to his distress. When he is thus discouraged, the principal outlet for his stress is psychoneurosis. It is probable that many of the Negro psychoneurotics fall into this group.

There is some correlation between the rates of chronic alcoholism (Table 10) and of psychopathy.

*Not community but individual figures.

In both cases, for instance, the Irish, Negroes and Italians, in varying order, are found to be the top three. But the rate for alcoholism among the Irish surpasses that of any other group. This variation cannot be explained in terms of socioeconomic level or

population density, for the Chinese, whose community is at least as dense and undesirable as those of the Irish, show an absence of alcoholism. Moreover, there is a marked difference between the Irish and the Italian communities in the rate for alcoholism, although there are no corresponding differences in density and desirability.

Alcohol among the Italians, Portuguese and Chinese is used primarily in the form of wine at mealtime and on festive occasions. It is seldom used in order to drown sorrow or to escape from physical and mental stress. Although wine may occasionally be taken to excess, the wine-drinking people have never been reported to have as much alcoholism as the hard liquor drinking nations of the north.

The Jews and the Chinese are lowest in the rate of alcoholism. The religion and culture of the Jews have restrained them from the social disgrace of drunkenness. The Chinese have not used alcohol as an emotional outlet, because to be drunk or disorderly brings shame on themselves and their families. (No Chinaman has yet been rejected for chronic alcoholism at this station.)

The high rate of alcoholism among the Negroes can be explained on the same basis as the high rate of psychopathy and psychoneurosis. The Negro is severely oppressed by all the types of stress mentioned; his impulse to aggressiveness is often in itself frustrated, and the result is that he is likely to become discouraged and broken. Alcoholism is an obvious outlet for this sort of stress, when alcohol is available.

The high rate of alcoholism among the Irish is less easily explained. It is known that alcohol has long been used freely by the Irish as a means of creating social conviviality after physical and nervous fatigue, and as a medicine, and its use in these ways has long been culturally acceptable. No other nationality in this study, with the possible exception of the Old American, uses alcohol in a manner similar to the Irish. The Old Americans, who are in a relatively secure social position, are subject to little or no abnormal stress and consequently are not in need of alcohol as an emotional outlet. We cannot determine to what extent alcohol would be used among the Old Americans were they under the same stress as the other groups. The Irish are subjected to a sufficient stress to permit an easy extension of their normal use of alcohol.

The rate of mental deficiency among the Chinese, Negroes, Italians and Portuguese (Table 11) is disproportionately high. Our figures are misleading, however, unless they are interpreted in terms of a number of racial and cultural factors.

Probably some of these findings can be attributed to the unavoidable limitations of our psychometric examination. We know that some members of these groups have resented being drafted and

the demands of the parents and the demands of society. Klineberg¹¹ remarks that the very fact that criminality "appears in the second and not in the first generation makes it clear that it cannot have a racial or biological basis, since this is obviously the same for both groups."

Large numbers of Italians, Negroes, Portuguese and Chinese have migrated from rural to urban communities. In rural communities there is little organized control of the individual's conduct other than that enforced by the social pressure of the group. The influence of law is unimportant, weak or resented. There is more respect for common labor, fewer broad class barriers based on material wealth, greater physical security and less concern for luxuries. These values are changed with movement into urban society. Because of the extent of adaptation necessary in the changing to a greatly divergent cultural pattern, this rural-urban shift usually brings cultural disorganization, with attendant increase in crime, delinquency, alcoholism, ambition and selfishness.

These stresses provide a plausible explanation of some of our findings. This is evident in racial and national variations in psychopathy and psychoneurosis, in the marked differences in the incidence of chronic alcoholism and in the disproportionately high rate of mental deficiency in some national groups. Sufficient data on the psychoses to warrant any generalization are not available.

The high incidence of psychopathy among the Negroes, Irish and Italians (Table 9) is easily explained. Each of these groups is subject to the stresses that accompany population density and low socioeconomic level. They are immigrant groups and, in varying degrees, have met with suspicion and hostility on the part of the Old Americans. Large numbers of them have undergone the disorganization involved in a rural-urban shift. The Italians, and particularly their children, — the

frustrations and deprivations mentioned above, as well as by many others. Psychopathy is the natural reaction to such stress, and it is acceptable in the undesirable communities from which most of the people come.

Since the Irish and the Italians have a culturally acceptable outlet in psychopathy, the rate of psychoneurosis is correspondingly low. It is lower among the Irish, possibly because they find a further outlet in alcoholism. Psychoneurosis is the primary cause of psychiatric rejection among the Portuguese, whereas psychopathy is the primary cause among the Irish and Italians. This probably can be explained in terms of socioeconomic level. The Irish and the Italians live in the most undesirable communities, and most of the Portuguese live in E and D communities. Although the E and D communities are low in desirability scale, it has been found that extreme psychopathy is to be expected only at the very lowest level, that is, in the truly slum areas.² Once one starts to move up the socioeconomic ladder, psychopathy becomes increasingly inhibited.

The low incidence of psychopathy, coupled with the high rate of psychoneurosis, among the Jews is not difficult to account for. The Jews seem to have acquired a special aptitude for adaptation to a new environment after centuries of migration into unfriendly surroundings. They have even devised special aids, such as the Hebrew Immigrant Aid Society, to smooth the early steps of adaptation for the immigrant, preventing his settling in the worst slums. The desirability level of their communities is higher than those of the Irish, Italians and Negroes. The stresses to which Jews are subjected in this area are not primarily those of frustration of their elementary physical needs, and consequently not such as to arouse psychopathy as a natural reaction. Further, their culture has been one dominated by a strong religion, which restrains them from asocial conduct. For centuries they have offered no military resistance to oppression. "I adjure you that if the government decrees harsh decrees, rebel not against any matter that it imposes upon you" (Ecclesiastes viii, 2). The asocial conduct of the psychopath has become culturally taboo and, as will be noted, the Jew is restrained from alcoholism. Accordingly, the principal outlet for his stress is psychoneurosis. Myerson⁶ attributes to the Jew "an apprehensiveness and an emotionality that arose from the conditions of life to which his Christian neighbors subjected him."

One of the interesting findings indicated in Table 9 is the comparatively low rate of psychopathy among the Chinese. The majority of the Chinese considered are subject to at least the same sources of stress as are the Irish and the Italians. They live in one of the densest and most undesirable communities, and are burdened by all the

*Not community but individual figures.

generation now being examined for induction, — have been submitted to a conflict between American society and the culture of their parents. The Negroes have been severely oppressed by all the

pressions of immigrant stress; they suffer from adjustment resulting from a rural-urban shift, larger numbers come from rural areas in China; they are deprived of many outlets by the presence of their families in China and by the shortage of Chinese women here. Yet the rate for psychopathy among them is comparatively low. This finding tends to indicate clearly the significance of racial factors in the etiology of mental disorders. Whether, in this case, the factors are biologic we cannot say, but it is clear that the culture of the Chinese has hindered both psychopathy and alcoholism unacceptable as outlets to stress. This rejection of violence is evident in the Chinese religious philosophy, which, like the religion of the Jews, serves to instill a deep respect for the law of the country. Psychoneurosis remains as the primary outlet for stress of the Chinese. Had those rejected for mental deficiency been able to express themselves more fully, psychoneurosis would probably have been found even oftener. (This error is not involved in the psychopathic or alcoholic groups, for adequate social-service records are available.)

The Negroes have the highest rate for both psychoneurosis and psychopathy. One reason for this may be that the Negroes in this study come from communities of varying densities and economic levels. A further and possibly more significant factor is the intensity and severity of the stress to which many of the Negroes are subjected. Aggressiveness is a natural reaction to physical stress, but when the stress is severe enough the individual is so completely oppressed that any impulse to aggressiveness is itself frustrated. When this happens the individual seldom hopes to overcome oppression and resigns himself to his distress. When he is thus discouraged, the principal outlet for his stress is psychoneurosis. It is probable that many of the Negro psychoneurotics fall into this group.

There is some correlation between the rates of chronic alcoholism (Table 10) and of psychopathy.

*Not community but individual figures.

In both cases, for instance, the Irish, Negroes and Italians, in varying order, are found to be the top three. But the rate for alcoholism among the Irish surpasses that of any other group. This variation cannot be explained in terms of socioeconomic level or

population density, for the Chinese, whose community is at least as dense and undesirable as those of the Irish, show an absence of alcoholism. Moreover, there is a marked difference between the Irish and the Italian communities in the rate for alcoholism, although there are no corresponding differences in density and desirability.

Alcohol among the Italians, Portuguese and Chinese is used primarily in the form of wine at mealtime and on festive occasions. It is seldom used in order to drown sorrow or to escape from physical and mental stress. Although wine may occasionally be taken to excess, the wine-drinking people have never been reported to have as much alcoholism as the hard liquor drinking nations of the north.

The Jews and the Chinese are lowest in the rate of alcoholism. The religion and culture of the Jews have restrained them from the social disgrace of drunkenness. The Chinese have not used alcohol as an emotional outlet, because to be drunk or disorderly brings shame on themselves and their families. (No Chinaman has yet been rejected for chronic alcoholism at this station.)

The high rate of alcoholism among the Negroes can be explained on the same basis as the high rate of psychopathy and psychoneurosis. The Negro is severely oppressed by all the types of stress mentioned; his impulse to aggressiveness is often in itself frustrated, and the result is that he is likely to become discouraged and broken. Alcoholism is an obvious outlet for this sort of stress, when alcohol is available.

The high rate of alcoholism among the Irish is less easily explained. It is known that alcohol has long been used freely by the Irish as a means of creating social conviviality after physical and nervous fatigue, and as a medicine, and its use in these ways has long been culturally acceptable. No other nationality in this study, with the possible exception of the Old American, uses alcohol in a manner similar to the Irish. The Old Americans, who are in a relatively secure social position, are subject to little or no abnormal stress and consequently are not in need of alcohol as an emotional outlet. We cannot determine to what extent alcohol would be used among the Old Americans were they under the same stress as the other groups. The Irish are subjected to a sufficient stress to permit an easy extension of their normal use of alcohol.

The rate of mental deficiency among the Chinese, Negroes, Italians and Portuguese (Table 11) is disproportionately high. Our figures are misleading, however, unless they are interpreted in terms of a number of racial and cultural factors.

Probably some of these findings can be attributed to the unavoidable limitations of our psychometric examination. We know that some members of these groups have resented being drafted and

as a result were not motivated to their best performance. Every practicable precaution against malingering is taken, but low motivation is important in borderline cases, and it is probable that

many who were rejected might have been accepted as borderline had they been better motivated. Further, although our psychologic tests are designed to measure intelligence or ability to learn, as distinguished from education or information, we cannot claim that this intention is realized in every case. The Chinese and, to a lesser extent, the Negroes and Portuguese seem to have insufficient familiarity with the materials from which some of the tests have been constructed, and this lack of familiarity may often result in an invalid performance.

Possibly the best cultural explanation of these findings is provided by the theory that apparent mental deficiency, in many cases, is merely a reaction to emotional stress. Dollard,¹² in his study of caste and class in southern towns, noted that the frustrated Negro, unable to find any aggressive outlet for his stress, unconsciously assumed an attitude of stupidity. In this way the completely discouraged individual was enabled both to incur revenge and to exempt himself from disagreeable responsibilities. Maslow and Mittelman¹³ insist that this apparent stupidity is an unconscious mechanism. They state: "This roundabout and inefficient path is chosen because the individual's fundamental needs have in one fashion or another been frustrated or come into conflict with one another. Give him back his self-esteem and his feeling of security, and his symptoms—whether apparent stupidity or hostility or compulsion—tend to disappear." The Laotian philosophy, as Lin Yutang has reminded us, has taught the Chinese that there is wisdom in "embracing folly."

Our figures concerning the Chinese are not strictly comparable with those of the other groups. It is not true that 24.5 per cent of the Chinese are feeble-minded. What this figure means is that this percentage of the Chinese were judged, in view of their apparently complete inability to understand

English, to have insufficient endowment to absorb Army training in the time provided for such purposes.

The low rate of mental deficiency among the Jews is not difficult to explain. Their stress is such as to provoke psychoneurosis. Unlike the Negroes, they are not so severely oppressed that they must resort to apparent stupidity as an exemption. Education has always been venerated by the Jews, since it has been necessary in their preservation under oppression ("Mine anointed are the school children. My prophets are the scholars."—*Chron.* xvi, 22). Their low rate on failure of mental tests can be attributed partly to their higher education, to the cultural opportunities afforded by their urban background and to their intense motivation to make high scores.

SUMMARY

At the Boston Armed Forces Induction Station the rejection rates for five types of mental disorders among seven different national or racial groups were determined.

The Negroes, Irish and Italians have high rates for psychopathic personality and chronic alcoholism; the Negroes, Chinese, Russian Jews and Portuguese for psychoneurosis; and the Chinese, Negroes, Italians and Portuguese for mental deficiency. The Negroes have high rates for all five types of disorder. The Old Americans have comparatively low rates.

These findings are partly explained in terms of the socioeconomic level, population density and the cultural differences of the different nationalities.

This study presents sufficient evidence of cultural differences as etiologic factors in mental disorders to suggest both the need of further investigation in this direction and the possibility of extensive application of mental hygiene.

PHYSICAL THERAPY IN WARTIME*

K. G. HANSSON, M.D.†

NEW YORK CITY

IN WARTIME most human endeavors are accelerated. This applies especially to medicine, and all the specialties are included. This paper attempts to discuss how physical therapy has come to war," and also points out lessons from the war that will undoubtedly influence civilian hospitals in the future. It is a pleasure to testify that it was Dr. Brackett and Dr. Goldthwait, of Boston, who were mainly responsible for the establishment of physical therapy in World War I, and that it was Dr. Granger, of Boston, who represented physical therapy in the Surgeon General's office during the last war.

During the present war, the Surgeon General is ordered that general and other large hospitals in the continental United States be provided with standard equipment for electrotherapy, hydrotherapy and thermotherapy, with gymnasium apparatus and with equipment for research. Most of the American hospitals in Alaska, Australia, Africa and Italy and at other operational bases are similarly equipped. These departments of physical therapy are under the direct supervision of one or more medical officers trained in this field. The aides must have the same training as that required by the American Medical Association, and were commissioned by an act of Congress in February, 1943. The Army has also assigned certain hospitals for specific treatment, such as the Walter Reed General Hospital for amputation cases, the Ashford General Hospital for arthritis, and the Fitzsimons General Hospital for rehabilitation.

The amount of work done in a physical-therapy department may be judged from the July, 1943, report from the Lawson General Hospital, where 10,056 treatments were given. The types of cases treated do not differ much from those in civilian life. They are back injuries, painful feet, knee injuries, strains, sprains, dislocations, fractures and burns. Now, however, since combat casualties are arriving, there is an increase in fractures, nerve injuries, burns and wounds of the soft tissue. The treatment of these cases is much the same as that in civilian hospitals, with special emphasis on whirlpool baths, occupational therapy, active exercises and massage.

Physical therapy in the Navy is similar to that in the Army, but owing to ship regulations much

of the work is done by more or less trained corpsmen or pharmacists' mates.

* * *

One of the outstanding contributions of the war so far has been the revision of convalescent care; this may be called rehabilitation, reconditioning or streamlined convalescence. The fact is that the uses and abuses of bed rest are being analyzed. It is evident that the increased supply of hospital beds, the development of the profession of nursing and the widespread use of hypnotics and narcotics are largely responsible for the present use of absolute bed rest. It has become familiar to all to see wards full of patients lying flat in bed, absolutely quiet and guarded against moving by nurses. The solid foundations of bed rest as a therapeutic measure, however, are being shaken, and absolute rest is being challenged. The facts that it costs \$20,000 to train a pilot and that it is more economical to cure such a patient than to train a new pilot may be the original cause of this revision of convalescence. It seems rational to review some of the factors concerning bed rest, and to describe certain of the physical-therapy measures to be used to discharge a patient in a better general condition than that when he entered the hospital. By discussing the various body systems separately, it may be possible to draw some conclusions concerning rest *versus* activity.

Skeleton. The posture that a patient assumes in bed is physiologically abnormal. A painful neck, an aching back and stiff knees are frequent symptoms of bed rest. Their occurrence can be prevented by the knowledge and application of proper body mechanics. Immobilization produces a negative calcium balance, which in turn may be counteracted by proper ultraviolet radiation every other day, either individually or, as is done at the New York Hospital, in specially built solariums equipped with powerful Finsen carbon arcs. Stiffness of the joints can be prevented by active or passive exercises at prescribed intervals.

Muscular system. The muscles are intended for activity, and when they are deprived of this, they become stiff, lose their tone and may go on to atrophy. Massage eliminates the lactic acid and carbon dioxide responsible for the stiffness, and muscle-setting exercises maintain tone and prevent atrophy.

Circulatory system. The circulatory system is probably the greatest sufferer from complete bed rest. Hyperemia, congestion and edema are frequent. It is less generally realized that constant

pressure on the veins in the calves may cause thrombosis, which in turn may be responsible for pulmonary emboli. Autopsies show that 30 per cent of all hospital patients have thrombi in the veins of the calves. In adults who have been in bed two weeks or longer, the incidence reaches 60 per cent. All show necrosis and inflammatory reactions in the calf muscles, which apparently initiate the process. Of the last 300 adult patients autopsied at the New York Hospital, 5 per cent died of pulmonary embolisms secondary to thrombi in the legs. This equals the number of deaths from cancer of the stomach, and the fatalities are considered due to complete bed rest. Such serious circulatory disturbance can be prevented by systematized exercises and changes of position in bed. This regime also maintains an adequate blood pressure and prevents dizziness when getting up.

Gastrointestinal system. The constipation of the bedridden patient is usually accepted as unavoidable, and many people ascribe their chronic constipation to previous confinement in bed. The objectionable bedpan is probably a contributory agent. The straining on a bedpan is probably underestimated, the danger of bathroom privileges is overestimated, and the result is that the patient becomes constipated from bed rest. It has been shown that there is no significant difference in the loss of energy from sitting as against that from lying flat in bed. In the Scandinavian countries abdominal massage is much in vogue to counteract constipation. If more abdominal massage were used, permission for sitting up and bathroom privileges were granted oftener and bedpans were less used, constipation from bed rest could be managed better than with the cathartic pill of some patent medicine.

Skin. Irritation of the skin is obvious and receives the immediate attention of the nurse. It has increased in frequency owing to the chemicals used in modern hospital laundries. Skin ulcers and bedsores are often considered the result of poor nursing, but bed rest is equally responsible. It is questionable whether the daily alcohol rub is the best solution, and whether it would not be physiologically sounder to use some fatty-acid application, together with changes in positions, and ultraviolet radiation.

Nervous system. Regarding the nervous system, the mind suffers most from being confined to one room and immobilized in bed. The rules of hospitalization regulate patients' days and nights so that they have no more responsibilities and have much time to feel sorry for themselves. At night, when darkness shuts out most external impressions,

painful sensations are increased. Occupational therapy is available to counteract many of the mental reactions of bed rest, and functional occupational therapy is most important to regain action.

* * *

In my visits to various reconditioning centers I have been impressed by this new conception of convalescence, but on closer inspection one finds that the medical officers are handicapped by a lack of trained personnel to carry out these ideas. The actual work of the convalescent program is usually carried out by men trained in physical education. They are all eager and enthusiastic, but the realization of these new rational ideas is not without danger. Great discrimination must be used in selecting the patients and the type of exercises to be employed. One gains the impression that the medical departments of the armed services have contributed a valuable advance in medical care, and it is to be hoped that this contribution can be put on a rational basis. Physical therapy has a very important part to play in this convalescent program. It is needless to point out that no radical departure from the rest treatment in tuberculosis, hypertension or comparable patients is advocated but this revision of the traditional hospitalization of patients must be considered in civilian practice. The advantage of the so-called "Kenny treatment" of poliomyelitis is not that it cures more patients than other methods but that the early application of activities turns out patients in better general health and with better circulation and muscular function than the old immobilization treatment produced.

Physical therapy has many contributions to offer when one considers the immediate necessity for shortening hospitalization, not only in the armed services but also in civilian life. It is high time to bring physical therapy into the wards of civilian hospitals. There has been a tendency to centralize it in a department. This is still necessary in many applications, such as hydrotherapy, mechanotherapy, underwater exercises, electrotherapy and so forth, but the time has come to attempt more active treatment of the bedridden patient. Physical therapy can be utilized to shorten the stay in bed, to counteract many deplorable results of bed rest and to turn out a discharged patient with more adequate circulation, better muscular tone, better posture, a normally functioning gastrointestinal tract, better skin and a mind that is mentally alert instead of depressed.

MEDICAL PROGRESS

PARENTERAL-FLUID THERAPY

The Estimation of Losses Incident to Starvation and Dehydration with Acidosis or Alkalosis and the Provision of Repair Therapy*

ALLAN M. BUTLER, M.D.,† AND NATHAN B. TALBOT, M.D.‡

BOSTON

THE first part of this review of parenteral-fluid therapy⁶⁷ the parenteral provision of the maintenance needs was considered. This deals with the parenteral repair of the losses of water and electrolyte incident to dehydration. For patient requiring parenteral therapy has suffered starvation and severe dehydration, the amount and type of the losses must be estimated, and appropriate repair needs must be provided parenterally in addition to the maintenance requirements.

CLINICAL APPRAISAL OF DEHYDRATION

The extent of the dehydration cannot be estimated reliably by any single laboratory procedure.⁵² Serial determinations of body weight, blood hemoglobin concentration,⁶⁸ red-cell and white-cell counts, plasma protein⁶⁹ and nonprotein nitrogen concentrations may contribute to a retrospective appraisal of the degree of the dehydration and the response to therapy, but even such serial determinations will not provide the pertinent information obtained by a careful history and physical examination and by the continued detailed clinical observation of the patient during therapy.

The history of weight loss, dietary and fluid intake and losses by urine, stool, vomiting, insensible sweating or other routes, together with the symptoms, indicate the nature and extent of the dehydration and fluid loss. In addition, they suggest probability of acidosis or alkalosis being associated with the dehydration.^{52, 70, 71}

By physical examination the clinical appraisal of the weight loss, tongue, mucous membranes, skin color, hydration of the eye and periocular tissue, heart action, peripheral circulation, fecal masses in the bowel, stools, urine volume and concentration. In the infant, the fontanelle further define the extent of the dehydration and starvation. Muscular hypertonicity, hyperactive reflexes, a positive Tostek or Trousseau sign or carpopedal spasm suggests alkalosis. Deep and exaggerated respirations confirm the probability of metabolic acidosis.⁷⁰⁻⁷⁴ or primary stimulation of the respiratory center with respiratory alkalosis.^{52, 70, 71, 73-76} In the case of extreme shock or emphysema, shallow irregular respirations support the probability of acidosis.^{52, 70, 71, 77, 78} Great caution must be taken

in using the urinary pH as an index of acidosis or alkalosis. Renal infection may render the urine alkaline in acidosis. In the dehydration of alkalosis the urine may be acid if the cation or sodium concentration of the plasma is below normal, as not infrequently occurs.^{70, 78}

Adequate nurse's notes detailing intake and output and signs and symptoms and frequent re-examination of the patient by the physician reveal much concerning the response to therapy.

In the early stages of appraisal and therapy, readily obtainable clinical information utilized with reasonable clinical judgment is far more valuable than the usually available laboratory determinations. Too often these latter in being substituted for clinical acumen provide little or misinterpreted information. For example, as discussed later and illustrated in Figure 1, a patient with an abnormally low plasma or blood carbon dioxide content may be suffering either from a metabolic acidosis — as in diarrhea or diabetic coma — or from a respiratory alkalosis — as in the hyperpnea of hysteria or encephalitis.^{52, 70, 71, 73-75, 77} As parenteral therapy proceeds, however, certain laboratory analyses, as discussed in the last section below, are guides essential to the provision of the best therapy.

Ordinarily, most of the weight loss during acute dehydration with starvation is due to loss of body water. Approximately half the loss comes from the extracellular fluids containing Na^+ , Cl^- and HCO_3^- , and half from the intracellular fluids containing K^+ , Mg^{++} , HPO_4^{--} , SO_4^{--} and protein.^{71, 79-84} A loss of between 8 and 12 per cent of the body weight represents significant dehydration. Hence the extracellular and intracellular losses may be estimated, as subsequently outlined in Table 1.

It is interesting that a relatively large intracellular fluid loss occurs following hemorrhage.⁸⁵

Rarely, when dehydration occurs at an extremely rapid rate with loss of the extracellular electrolytes Na^+ and Cl^- , — as occurs in a hot box or under anesthesia in a hot operating room or by loss of interstitial fluid while ingesting water, — the plasma volume may be reduced so rapidly that circulatory collapse occurs before marked generalized dehydration has an opportunity to develop.^{69, 80, 86}

EXTRACELLULAR LOSSES AND REPAIR

Qualitatively, the extracellular losses vary with the route of loss.^{70, 71, 87-89} For example, in vomiting

321 East 42d Street

tion of sodium chloride higher or lower than the normal serum sodium and chloride concentrations of 322 and 365 mg. per 100 cc. respectively? Or, if a 0.85 per cent solution of sodium chloride is infused fairly rapidly into a dehydrated patient whose kidneys are not functioning adequately, as indicated by an elevated nonprotein nitrogen, will the serum Cl^- level tend to be elevated or lowered? And if the serum Cl^- level is lowered or elevated by 35 mg. per 100 cc., by how many volumes per cent will the carbon dioxide tend to be changed? Perhaps to answer this, one would need to know the effect of the infused saline on the serum Na^+ concentration. These, of course, are questions that everyone can answer readily, because one could hardly use physiologic saline solution parenterally without knowing the answers. But the answers are readily given because, instead of the difficultly integrated units of concentration used above, a single unit of chemical equivalents is generally used in expressing the concentrations of electrolytes in body fluids. The utilization of chemical equivalents as the unit of concentration is logical, because the demand of electroneutrality of the body fluids prescribes an equality or balance of the sum of the electropositive ions (cations) and the sum of the electronegative ions (anions). This unit therefore permits visualization and appraisal of the disturbances in the balance of cations (bases) and anions (acids) in which one is clinically interested. Custom and the order of magnitude of these concentrations in body fluids render the milliequivalent† per liter of solution or per liter of water a convenient and accepted unit of concentration in clinical medicine, as evidenced by all the references given in this review. In considering the equilibrium of electrolytes in the different compartments of body fluids, concentrations expressed as milliequivalents per liter of water are preferable, but the more easily determined milliequivalents per liter of solution suffice for considerations of parenteral fluid therapy.

The accepted normal plasma concentrations in milliequivalents per liter of plasma are as follows:

CATIONS		ANIONS	
Na	138	HCO_3^-	26
K	5	Cl	103
Ca	5	HPO_4^-	2
Mg	2	SO_4^-	1
		Organic acid	2
		Protein	16
Total	150	Total	150

*The custom of expressing plasma Cl concentrations as milligrams of sodium chloride per 100 cc. is, of course, illogical, since the Na and Cl concentrations of plasma are not equal.

The carbon dioxide dissolved as undissociated carbonic acid is normally 1.3 millimoles per liter. As the total carbon dioxide determined in the clinical laboratory is the sum of this dissolved carbon dioxide and the HCO_3^- , the normal total plasma

carbon dioxide equals 1.3 plus 26, or approximately 27 millimoles per liter.

Physiologic saline (0.85 per cent sodium chloride) solution contains 145 milliequiv. of Na^+ and 145 milliequiv. of Cl^- per liter.

Using the milliequivalent one can readily appreciate, as shown by the diagrams in Figures 1 and 2, that the Cl^- concentration of physiologic saline solution is appreciably higher than that of normal serum. Therefore, the infusion of such saline solution tends to elevate the serum Cl^- level. This of course tends to lower the HCO_3^- and thus the total carbon dioxide level, a rise of 10 milliequiv. Cl^- tending to effect a 10-milliequiv. lowering of the HCO_3^- . Since the normal HCO_3^- concentration is but 26 milliequiv. per liter, this is a significant reduction. Such an infusion of physiologic saline solution, however, has but little effect on the serum Na^+ concentration. Since the milliequivalent makes all this clear, it is odd that physicians have often resented rather than welcomed its use.

Gamble's⁹⁷ graphic presentation of the anatomy and vicissitudes of the extracellular fluids^{74, 98} profusely illustrates how the milliequivalent facilitates the clinical appraisal of a patient's status with respect to cation-anion equilibrium, — that is, acidosis and alkalosis, — and thus simplifies clinical thought concerning electrolyte and water metabolism.

Such graphic presentation of the composition of normal plasma and of the plasmas of patients suffering from the dehydration, starvation and metabolic alkalosis of gastric vomiting, from the respiratory acidosis of asthma, from the dehydration, starvation and metabolic acidosis of severe diarrhea and from the respiratory alkalosis of primary hyperventilation is presented in Figure 1. Figure 2 similarly presents the composition of physiologic saline solution, of 1/7 molar sodium bicarbonate solution

†An equivalent is the weight of an ion which, in neutralization reactions, is equivalent to 1 gram-atom of hydrogen. Thus, the number of milliequivalents per liter is equal to the milligrams per 100 cc. times ten divided by the equivalent weight, which, in turn, is the atomic weight divided by the valence. For example,

$$322 \text{ mg. sodium per } 100 \text{ cc.} = \frac{322 \times 10}{23} = 140 \text{ milliequiv. Na per liter.}$$

$$365 \text{ mg. chloride per } 100 \text{ cc.} = \frac{365 \times 10}{35.5} = 103 \text{ milliequiv. Cl per liter.}$$

$$10 \text{ mg. calcium per } 100 \text{ cc.} = \frac{10 \times 10}{20} = 5 \text{ milliequiv. Ca per liter.}$$

$$60 \text{ vol. per cent carbon dioxide} = \frac{60 \times 10}{22.4} = 27 \text{ millimoles carbon dioxide.}$$

per liter, where 22.4 equals the liters of carbon dioxide that at 0°C. and 1 atmosphere of pressure contain 1 mol of carbon dioxide. In normal plasma, in which the ratio of HCO_3^- to H_2CO_3 is 20:1, 27 mm. of carbon dioxide per liter is equal to 1.3 mols of carbonic acid plus 25.7 milliequiv. of HCO_3^- per liter. Therefore, the following approximation satisfies clinical purposes:

$$\frac{\text{Vol. per cent carbon dioxide}}{2.3} = \text{milliequivalents } \text{HCO}_3^- \text{ per liter.}$$

there is a greater loss of Cl^- than of Na^+ , with a resultant tendency to alkalosis.^{77, 90} The alkalosis organic and organic acid catabolites and a diminution in the renal excretion of cations (bases)

FIGURE 1. Diagrammatic Representation (according to Gamble) of the Electrolyte Composition of the Plasma of a Normal Subject, a Patient with the Metabolic Alkalosis of Gastric Vomiting, a Patient with the Respiratory Acidosis of Asthma, a Patient with the Metabolic Acidosis of Severe Diarrhea and a Patient with the Respiratory Alkalosis of Hysterical Hyperventilation.

The numerical values for Na, HCO₃ and Cl represent milliequivalents per liter. The sums of other cations and anions are given merely to show their relative order of magnitude and direction of change in concentration. Similarly the undissociated mols of carbonic acid are diagrammed roughly to indicate the direction of change. The reaction (pH) is proportional to the ratio of the HCO₃ to the carbonic acid.^{52, 70, 71}

is then partially compensated by the excretion of Na^+ and K^+ with HCO_3^- in an alkaline urine.⁹¹

TABLE 1. Calculations for Approximating the Extracellular Parenteral Needs, Over and Above the Maintenance Needs, of Dehydrated Acidotic Patients.

CONSIDERATION	5-KG. INFANT	60-KG. ADULT
Fluid loss:		
Weight before dehydration	5000 gm.	60000 gm.
Weight after dehydration	4400 gm	54000 gm.
Approximate total fluid loss	600 cc.	6000 cc.
Extracellular loss = half total loss . . .	300 cc.	3000 cc.
Intracellular loss = half total loss . . .	300 cc.	3000 cc.
Provision of repair needs:		
One part M/7 sodium bicarbonate* + two parts physiologic saline solution for extracellular loss and acidosis . .	300 cc.	3000 cc.
Serum for protein depletion†	100 cc.	800 cc.
Whole blood for hemoglobin and protein depletion‡	100 cc.	500 cc.

*Or M/7 sodium lactate.
†To be given if the serum protein level is low before or during parenteral therapy.
‡To be given if the red-cell count or hemoglobin level and serum protein level are low before or during parenteral therapy.

As the dehydration progresses the renal function is impaired,^{92, 93} with a resultant retention of in-

bicarbonates.^{70, 78} In diarrhea two factors dispose to acidosis. First, there is a greater in diarrheal stools of sodium and other cat (bases) than of chloride and other anions (acids). Second, the impaired renal function incident to dehydration results in the retention of acid ca olites.^{70, 71, 87, 88, 96} Starvation ketosis tends develop in both the alkalotic dehydration of vo ing and the acidotic dehydration of diarrhea.

Diagrammatic visualization of the disturba in the balance of cations (bases) and anions (ac greatly facilitates comprehension of the pathol physiology of the extracellular fluids.⁷¹ Utiliza of unrelated units of concentration, such as n grams per 100 cc. of chloride and volumes per of carbon dioxide for serum and grams of sod chloride per 100 cc. for physiologic saline s tion, makes such visualization impossible and ders thinking difficult. For example, are the l and Cl^- concentrations of a 0.85 per cent s

days when sterile sodium bicarbonate and sodium lactate solutions¹⁰⁴ were available, 10 per cent dextrose was added to the physiologic saline solution to so increase blood flow and improve renal function that the excess Cl^- could be excreted promptly.^{88, 95} The resulting increase in urine volume favored the urinary excretion of Cl^- , nonprotein nitrogen and other catabolites and the acidosis was ultimately corrected. Fortunately, sterile solutions of sodium bicarbonate or sodium lactate are readily available today. Therefore physiologic saline solution may be so diluted with these solutions that its hypertonicity in Cl^- is corrected and efficient hydration of the acidotic patient may be accomplished without delay in correcting the acidosis and hyperpnea. For example, the third diagram in Figure 2 depicts the concentrations obtained by diluting two parts of 0.85 per cent saline solution with one part of 1/7 molar sodium bicarbonate solution. Because this mixture has an HCO_3^- content almost double that of normal plasma, — that is, 48 milliequiv. per liter, — its infusion to a dehydrated acidotic patient with a low plasma HCO_3^- level and pH (fourth diagram Fig. 1) elevates the lowered plasma and extracellular bicarbonate and thus tends to correct the acidosis. At the same time, because the Na^+ and Cl^- concentrations of this mixture approximate those of normal plasma, it favors the restoration of normal serum Na^+ and Cl^- concentrations while repairing the deficit of extracellular electrolytes. One-seventh molar sodium lactate solution may usually be substituted for the NaHCO_3 solution, since the lactate ion appears to be oxidized to HCO_3^- rapidly enough to meet the needs and has the possible advantage of being easy to prepare and nonirritating when given subcutaneously.¹⁰⁴ A greater dilution of physiologic saline solution by bicarbonate or lactate does not appear either necessary or desirable.

The calculation of the bicarbonate requirement, as sometimes done from the plasma carbon dioxide* and weight of the patient,^{89, 104, 105} involves the assumption that the bicarbonate contents of extracellular and intracellular fluids are equal. Since it has been shown that no such equality exists,^{106, 107} the calculation may involve a 50 per cent error and therefore is hardly worth while. Moreover, the amount of molar sodium bicarbonate that results in a given effect on the serum carbon dioxide has been shown to vary in different patients.¹⁰⁸ Physiologically it appears sounder to appraise the need of bicarbonate by careful clinical appraisal of the metabolic disturbance and respirations as indicated by the history and physical findings.

In appraising acidosis by hyperpnea it should be remembered that hyperpnea may be of central-

*Assuming that total plasma carbon dioxide per liter times 19/20 equals body fluid HCO_3^- per liter and that liters of body fluid equal kilograms body weight times 0.70.

nervous-system, not metabolic, origin. Primary hyperventilation of such origin, although resulting in a diminished total plasma or blood carbon dioxide, is associated with an alkalosis, not an acidosis.^{52, 70, 71, 73-77} The fifth diagram in Figure 1 depicts the plasma of a patient with primary hyperpnea and hence respiratory alkalosis. The HCO_3^- is diminished just as in the patient with the metabolic acidosis of diarrhea, but the pH is elevated and the patient is suffering from an alkalosis. This limitation in the diagnostic information provided by such a carbon dioxide determination is clearly illustrated by the diagrams of Figure 1. The second and third demonstrate that there can be either an alkalosis or an acidosis with an elevated HCO_3^- or total carbon dioxide. The fourth and fifth show that either an alkalosis or acidosis may be accompanied by a low HCO_3^- or total carbon dioxide. Similarly it should be noted that an alkalosis may be present with either a diminished or elevated serum Cl^- , as illustrated in the second and fifth diagrams. The significance of analysis of carbon dioxide or Cl^- depends on a proper correlation of the history and physical findings.

If the metabolic disturbance is a type that predisposes to acidosis, — for example, diarrhea or diabetic coma, — the degree of hyperpnea provides an index of the severity of the acidosis except in the premature, the newborn or the patient in shock.^{52, 72} Both the dehydration and acidosis are corrected by the infusion of a mixture of one part 1/7 molar sodium bicarbonate or lactate and two parts 0.85 per cent saline solution at the rate appropriate for hydration of the patient concerned — in other words, at the rate appropriate for the infusion of physiologic saline solution. The amount of this mixture infused is determined by the duration of the hyperpnea. Usually after one to two hours, when the gross hyperpnea has abated, physiologic saline solution may be substituted for the mixture of alkali and saline solution, since at such time the acidosis is no longer extreme and the extracellular hydration has so improved the blood flow and renal function as to permit the selective renal excretion of Cl^- above that of Na^+ and thus the elimination of the excess Cl^- of the saline solution.

The actual manner of estimating the parenteral extracellular repair therapy for an infant and for an adult suffering from acute nutritional failure with diarrhea, dehydration, acidosis and inability to take food and fluids orally is illustrated by the data of Table 1. The indicated repair therapy is of course provided in addition to the required maintenance needs, as stated in the previous article.⁶⁷

As already mentioned, the extracellular loss approximates one half the total weight loss or from 4 to 6 per cent of the patient's weight. The extracellular repair needs are easily provided by the intravenous or subcutaneous administration of

and of a mixture consisting of two parts of the former and one of the latter.

In Figure 1, the diagram of the plasma of a patient with gastric vomiting and excessive loss of chloride shows an abnormally low plasma chloride concentration. Ketone acids, which have accumulated as a result of the starvation, partially replace the loss in Cl^- . The HCO_3^- has increased to balance the Na^+ left uncovered by the Cl^- deficit. The history of gastric vomiting and the resulting elevation in HCO_3^- concentration above normal indicates a metabolic alkalosis. But it is important

trations resulting from gastric vomiting.^{52, 70, 71, 77, 87, 90, 100} The choice between 5 and 10 per cent dextrose depends on the amount of solution to be infused. In moderate dehydration, in which the rate of infusion is relatively slow and the total amount moderate, 10 per cent is required to meet the caloric requirements specified for maintenance needs, as noted in the previous article.⁶⁷ However, in severe dehydration, in which a more rapid initial rate of infusion is indicated to repair the dehydration, the initial use of 5 rather than 10 per cent dextrose in saline solution appears preferable to avoid

to note that without the history and physical findings the change in HCO_3^- concentration, as measured by the total carbon dioxide, could not establish such a diagnosis. Thus, although the plasma of a patient with emphysema (Fig. 1) had a similar increase in HCO_3^- and lowering of Cl^- ,^{70, 71, 73, 98, 99} the latter had an acidosis not an alkalosis. The determination of the serum pH, however, permits this differentiation by chemical means alone.

To treat the case of gastric vomiting, the infusion of 0.85 per cent saline solution, which contains no HCO_3^- and approximately one and a half times more Cl^- than plasma (Fig. 2), tends to increase the low plasma Cl^- , to decrease the elevated plasma HCO_3^- and thus to correct the hypochloremia and alkalosis. The simultaneous infusion of 5 or 10 per cent glucose limits the starvation and reduces the ketosis. Thus, 5 or 10 per cent dextrose in 0.85 per cent saline solution provides an initial parenteral-fluid therapy that is almost ideal for correcting the dehydration and disturbed plasma and extracellular fluid concen-

excessive hyperglycemia and glycosuria. The greater volume of fluid administered under such conditions of dehydration offsets the diminution in concentration.

The foregoing considerations indicate that the lack of HCO_3^- and the hypertonicity of Cl^- in physiologic saline solution relative to the Cl^- concentration of normal plasma (Figs. 1 and 2) render physiologic saline solution inappropriate as the initial parenteral therapy for correcting the disturbed plasma and extracellular fluid concentrations resulting from dehydration and acidosis. Inspection of the first and fourth diagrams in Figure 1 and the first diagram in Figure 2 should make this clear.

There is ample evidence^{87, 89, 101-103} that the infusion of 0.85 per cent saline solution in an acidotic dehydrated patient whose renal function is impaired by the dehydration, as evidenced by an elevated nonprotein nitrogen and other abnormal serum concentrations, may raise the plasma Cl^- above normal and thus prevent increase in the HCO_3^- and alleviation of the acidosis and hyperpnea. Before the

days when sterile sodium bicarbonate and sodium lactate solutions¹⁰⁴ were available, 10 per cent dextrose was added to the physiologic saline solution to so increase blood flow and improve renal function that the excess Cl^- could be excreted promptly.^{88, 95} The resulting increase in urine volume favored the urinary excretion of Cl^- , nonprotein nitrogen and other catabolites and the acidosis was ultimately corrected. Fortunately, sterile solutions of sodium bicarbonate or sodium lactate are readily available today. Therefore physiologic saline solution may be so diluted with these solutions that its hypertonicity in Cl^- is corrected and efficient hydration of the acidotic patient may be accomplished without delay in correcting the acidosis and hyperpnea. For example, the third diagram in Figure 2 depicts the concentrations obtained by diluting two parts of 0.85 per cent saline solution with one part of 1/7 molar sodium bicarbonate solution. Because this mixture has an HCO_3^- content almost double that of normal plasma, — that is, 48 milliequiv. per liter, — its infusion to a dehydrated acidotic patient with a low plasma HCO_3^- level and pH (fourth diagram Fig. 1) elevates the lowered plasma and extracellular bicarbonate and thus tends to correct the acidosis. At the same time, because the Na^+ and Cl^- concentrations of this mixture approximate those of normal plasma, it favors the restoration of normal serum Na^+ and Cl^- concentrations while repairing the deficit of extracellular electrolytes. One-seventh molar sodium lactate solution may usually be substituted for the NaHCO_3 solution, since the lactate ion appears to be oxidized to HCO_3^- rapidly enough to meet the needs and has the possible advantage of being easy to prepare and nonirritating when given subcutaneously.¹⁰⁴ A greater dilution of physiologic saline solution by bicarbonate or lactate does not appear either necessary or desirable.

The calculation of the bicarbonate requirement, as sometimes done from the plasma carbon dioxide* and weight of the patient,^{89, 104, 105} involves the assumption that the bicarbonate contents of extracellular and intracellular fluids are equal. Since it has been shown that no such equality exists,^{106, 107} the calculation may involve a 50 per cent error and therefore is hardly worth while. Moreover, the amount of molar sodium bicarbonate that results in a given effect on the serum carbon dioxide has been shown to vary in different patients.¹⁰⁸ Physiologically it appears sounder to appraise the need of bicarbonate by careful clinical appraisal of the metabolic disturbance and respirations as indicated by the history and physical findings.

In appraising acidosis by hyperpnea it should be remembered that hyperpnea may be of central-

nervous-system, not metabolic, origin. Primary hyperventilation of such origin, although resulting in a diminished total plasma or blood carbon dioxide, is associated with an alkalosis, not an acidosis.^{52, 70, 71, 73-77} The fifth diagram in Figure 1 depicts the plasma of a patient with primary hyperpnea and hence respiratory alkalosis. The HCO_3^- is diminished just as in the patient with the metabolic acidosis of diarrhea, but the pH is elevated and the patient is suffering from an alkalosis. This limitation in the diagnostic information provided by such a carbon dioxide determination is clearly illustrated by the diagrams of Figure 1. The second and third demonstrate that there can be either an alkalosis or an acidosis with an elevated HCO_3^- or total carbon dioxide. The fourth and fifth show that either an alkalosis or acidosis may be accompanied by a low HCO_3^- or total carbon dioxide. Similarly it should be noted that an alkalosis may be present with either a diminished or elevated serum Cl^- , as illustrated in the second and fifth diagrams. The significance of analysis of carbon dioxide or Cl^- depends on a proper correlation of the history and physical findings.

If the metabolic disturbance is a type that predisposes to acidosis, — for example, diarrhea or diabetic coma, — the degree of hyperpnea provides an index of the severity of the acidosis except in the premature, the newborn or the patient in shock.^{52, 72} Both the dehydration and acidosis are corrected by the infusion of a mixture of one part 1/7 molar sodium bicarbonate or lactate and two parts 0.85 per cent saline solution at the rate appropriate for hydration of the patient concerned — in other words, at the rate appropriate for the infusion of physiologic saline solution. The amount of this mixture infused is determined by the duration of the hyperpnea. Usually after one to two hours, when the gross hyperpnea has abated, physiologic saline solution may be substituted for the mixture of alkali and saline solution, since at such time the acidosis is no longer extreme and the extracellular hydration has so improved the blood flow and renal function as to permit the selective renal excretion of Cl^- above that of Na^+ and thus the elimination of the excess Cl^- of the saline solution.

The actual manner of estimating the parenteral extracellular repair therapy for an infant and for an adult suffering from acute nutritional failure with diarrhea, dehydration, acidosis and inability to take food and fluids orally is illustrated by the data of Table 1. The indicated repair therapy is of course provided in addition to the required maintenance needs, as stated in the previous article.⁶⁷

As already mentioned, the extracellular loss approximates one half the total weight loss or from 4 to 6 per cent of the patient's weight. The extracellular repair needs are easily provided by the intravenous or subcutaneous administration of

*Assuming that total plasma carbon dioxide per liter times 19/20 equals body fluid HCO_3^- per liter and that liters of body fluid equal kilograms body weight times 0.70

the saline and bicarbonate or lactate solutions. The intravenous administration is usually preferable because it results in less discomfort to the patient than administration by clysis and permits giving with the saline and sodium bicarbonate or lactate solutions the 5 or 10 per cent dextrose that is needed to provide the calories essential for the maintenance requirements.* In considering the administration of dextrose to the dehydrated acidotic patient, just as with the alkalotic one, 5 per cent dextrose appears preferable to 10 per cent in the initial parenteral therapy because the desirable rate of infusion in the initial phase of such therapy exceeds that at which 10 per cent dextrose can be administered without causing excessive hyperglycemia and glycosuria.

The application of these general principles to the initial parenteral therapy of the patient in diabetic coma is apparent. Because the literature is large and the issues somewhat confused, the parenteral therapy of such patients will be considered in a separate review of the therapy of diabetic coma.

INTRACELLULAR LOSSES AND REPAIR

Although the quantitative importance of intracellular losses incident to dehydration is evident,^{71, 79-84} little is known about their qualitative differences according to the manner of the dehydration and the occurrence of intracellular alkalosis or acidosis.^{106, 109}

Such transfusions of whole blood or plasma as are specified in Table 1 are given primarily to sustain red-cell and plasma volumes and plasma protein concentration. Some recent evidence indicates that plasma transfusions may be less effective in maintaining blood and plasma volumes than are whole-blood transfusions⁵³⁻⁵⁵; however, they provide some cellular nourishment, although the amount so provided is small. Recent observations concerning carbonic anhydrase¹¹⁰ suggest another advantage of whole blood over plasma. Carbonic anhydrase is an enzyme that accelerates the splitting of carbonic acid to form carbon dioxide and water. The enzyme is present in red cells¹¹¹ and is inhibited by serum.¹¹² The low concentrations of carbonic anhydrase observed in premature and newborn infants¹¹³ increase following transfusions of adult blood.¹¹³ Thus it has been suggested that whole-blood transfusions have a particular role in treating the acidosis and cyanosis of the newborn.¹¹³

Ringer's solution contains so few of the intracellular electrolytes that its administration accomplishes little more than giving an unwarranted feeling of satisfaction to the physician and causing expense to the hospital or patient. The provision of amino acids is included in the recommended maintenance therapy given in the first article.⁶⁷ The amounts specified barely cover normal main-

tenance requirements. In extremely depleted patients or patients sustaining severe nitrogen losses incident to burns⁷ or shock,^{6, 8-10} larger amounts of amino acids may be indicated.

But the addition of such intracellular parenteral therapy to the routine extracellular parenteral solutions does not provide the PO_4^{--} , K^+ , Mg^{++} and Ca^{++} that have been lost by these depleted patients and that are essential to a resumption of normal cellular metabolism. Therefore, until the present limitations in providing these substances parenterally are overcome, it is important to start oral feedings as soon as this can be accomplished without nausea or diarrhea.^{52, 89} Since adequate dextrose, extracellular constituents and intracellular crystalline enzymes or vitamins can be given parenterally, the oral feedings should provide readily digested foods, containing nitrogen, potassium, phosphate, magnesium and calcium. Beef broth, diluted milk and properly flavored amino acid preparations, if not nauseating, are suitable.

An acute nutritional disturbance, particularly in infants, is not infrequently accompanied by a diminution in gastric acidity and invasion of colon bacilli into the stomach. The dilution and acidification of fat-free milk with a lactate buffer (pH 3) has been advocated as a means of facilitating acid gastric digestion and restoring normal gastric acidity when milk feedings are started.¹¹⁴ Whether or not the sodium content of this buffer makes it superior to lactic acid appears to depend on the patient's need for extracellular base. Attention has recently been called to the possible danger of overacidification.¹¹⁵ The addition of ascorbic acid and members of the vitamin B complex to the oral feedings of depleted patients seems desirable.

It is frequently advantageous to start small oral feedings for intracellular repair before the parenteral fluid therapy is discontinued. In so doing some of the essential intracellular nutrients can be provided early with a minimal demand on gastrointestinal function. As the patient demonstrates an ability to handle the oral feedings, they are increased in amount and the parenteral fluids are eliminated.

CHECKING THE STATE OF THE PATIENT

Although careful observation of fluid intake, urine volume, number and volume of stools, respirations, pulse, temperature (including the extremities) and state of hydration by physical examination is essential and invaluable,⁵² adequate appraisal of the state of a previously depleted patient who has been nourished only by parenteral fluids for longer than twenty-four hours is difficult without the aid of chemical analyses of the blood. This is particularly true in the presence of continuing vomiting, diarrhea or the loss of gastric and intestinal juices by other routes.

Determination of whole-blood hemoglobin and the serum concentration of roten indicates the

*Although 5 per cent dextrose may be given subcutaneously in the dehydrated patient it not only may be absorbed very slowly but also may in the process of absorption remove extracellular fluid.^{82, 108}

of whole blood or serum, initially or in the course of parenteral-fluid therapy. Comparison of serial or daily hemoglobin and protein values reveals the trend in the patient's water balance and need of fluid.^{68, 69} The relative adequacy of renal excretion and function may be appraised by determining the nonprotein nitrogen concentration. The presence of chloride depletion with increased serum CO_3^- concentration, alkalosis and the need of physiologic saline solution, or the presence of base deficit with a decreased serum HCO_3^- level, acidosis and the need of the combination of sodium carbonate (or lactate) and saline solution, may be determined initially or checked during therapy by analyses of the serum concentrations of chloride and either sodium or carbon dioxide. However, as already mentioned, a careful interpretation of the laboratory and clinical findings is necessary before the carbon dioxide content of the serum can be used as an index of alkalosis or acidosis. Indeed, a critical appraisal that permits interpretation of the carbon dioxide concentration usually means that the actual determination of the carbon dioxide attributes but confirmatory information. The presence of acidosis or alkalosis may be definitely established by determining the serum or whole-blood pH.

The amounts of blood or serum required for these analyses are as follows: hemoglobin, 0.02 cc of whole blood¹¹⁶; serum protein, 0.02 cc.¹¹⁷; non-protein nitrogen, 0.1 cc. of whole blood or serum¹¹⁸; serum chloride 0.5 cc.¹¹⁹; serum sodium, 0.5 cc.¹²⁰; serum carbon dioxide, 0.5 cc.¹²¹; and pH, 0.2 cc.¹²²

SUMMARY

The parenteral therapy of the patient unable to take fluids or food by mouth has been reviewed. The first part of this review outlined the estimation of maintenance requirements and the provision of maintenance therapy under the separate categories of water, sodium chloride, nitrogen and calories. In the second, part considers the estimation of the losses incident to starvation and dehydration and the provision of repair therapy. It specifically deals with the clinical appraisal of the dehydration and the accompanying acidosis or alkalosis; extracellular losses and their repair; intracellular losses and repair; and checking the state of the patient and his needs by blood analyses.

The importance of providing the therapy described under all these categories is emphasized. It is hoped that this manner of review provides physiologic concepts and therapeutic measures that may be integrated by the physician to meet the needs of each patient.

The data tabulated under each category are applicable to the parenteral therapy of infants, children and adults. The requirements of sodium chloride for maintenance and for repair are reviewed separately to emphasize their different orders

of magnitude. Appreciation of this difference should avoid oversalting the patient requiring only maintenance therapy and undersalting the patient requiring extensive extracellular repair therapy. The possible need of providing 10 to 15 per cent dextrose in maintenance parenteral therapy where relatively moderate total volumes of solution are infused at a slow rate is indicated. On the other hand, where a larger volume of repair solution is being rapidly infused in the initial therapy of severe dehydration, a concentration of 5 per cent dextrose in the parenteral fluid appears to provide a total amount adequate to meet the caloric requirements. The suitability of using 0.85 per cent saline solution in the parenteral therapy of the dehydrated alkalotic patient is described. The inappropriateness of such a solution in the initial parenteral therapy of the dehydrated acidotic patient and the desirability of substituting a mixture of one part 1/7 molar sodium lactate or bicarbonate solution and two parts physiologic saline solution are emphasized. The simplification of thought concerning disturbances in water and electrolyte balance provided by utilization of the milliequivalent as the unit of concentration is illustrated.

Attention is called to the importance of intracellular losses in dehydration and starvation and to the inadequacy of present-day parenteral therapy to repair such losses. The administration of appropriate food orally early during the course of therapy is emphasized.

CASE 30441

PRESENTATION OF CASE

A seventy-nine-year-old man entered the hospital for study.

For many years before admission the patient complained of urinary symptoms, including frequency and nocturia (six to eight times). There was diminution in the caliber and strength of the urinary stream, with dribbling and intermittency of urination. Six years prior to entry he was told that he had "prostatic trouble." During the few months before admission his urinary difficulties increased in severity.

*On leave of absence.

The past history revealed that the patient had a moderate tremor of the extremities for thirty years and of the head and voice for two years.

Physical examination revealed a well-developed and well-nourished man in no obvious distress. There was bilateral arcus senilis. There was a gross tremor of the head. The chest was moderately emphysematous. The lungs were clear to auscultation and percussion. The heart was slightly enlarged to the left on percussion. The rhythm was normal. There were no murmurs or thrills. Multiple extrasystoles were heard over the apex. The abdomen was negative, except that the bladder was distended, reaching to 5 cm. below the umbilicus. The prostate was twice the normal size, nontender, resilient and movable. There were marked tremors of the extremities and of the voice. Neurologic examination was negative.

The blood pressure was 240 systolic, 104 diastolic. The temperature was 98.6°F., the pulse 80, and the respirations 20.

Examination of the blood showed a red-cell count of 4,750,000, with a hemoglobin of 85 per cent. The white-cell count was 9400. The urine showed a + to +++ test for albumin; the sediment contained innumerable red cells, and a culture revealed abundant *Staphylococcus albus*. The nonprotein nitrogen was 35 mg. per 100 cc.

An x-ray film of the chest showed a slight amount mottled, increased density in the left upper lobe and the first interspace. The bases of both lungs were emphysematous. There was a rounded area of calcification 1 cm. in diameter at the right base, which was thought to represent a Ghon lesion. The diaphragm was low in position. There was no prominence of the left ventricle, but the thoracic ratio was 14:30. An intravenous pyelogram was negative.

On the third day the patient suddenly complained of severe, nonradiating subxiphoid pain accompanied by slight nausea and, two hours later, vomiting. Physical examination revealed an occasional extrasystole in a slightly enlarged heart, with otherwise regular rhythm. There were a split mitral second sound and a faint apical systolic murmur. The lungs were clear. There was no evidence of cardiac failure, and the patient was not cyanotic. The epigastrium was not tender. The legs were normal. The blood pressure was 260 systolic, 120 diastolic. The patient was confined to bed and given 11 mg. ($\frac{1}{4}$ gr.) of morphine. The pain lasted two hours and then subsided.

Two days later an electrocardiogram revealed a normal rhythm, with a rate of 60, a PR interval of 0.17 second, a slightly sagging ST segment, an upright T_1 , a low upright T_2 and a small Q_2 (2 mm.) and Q_3 (3 mm.), with deep late inversion of T_2 ; the precordial leads showed upright T waves, with slightly sagging ST segments in CF_4 and CF_5 . The blood pressure was 150 systolic, 60 diastolic. The corrected sedimentation rate was 1.8 mm. per minute.

An electrocardiogram taken on the seventh day after admission revealed a normal rhythm, with a rate of 60, a PR interval of 0.17 second, sagging ST_1 and ST_2 , an upright T_1 , diphasic T_2 and T_3 and small Q_2 and Q_3 ; the precordial lead showed an upright T wave. An electrocardiogram taken fourteen days after admission showed normal rhythm, with a rate of 80, a PR interval of 0.16 second, an upright T_1 , a flat T_2 , an inverted T_3 , small Q_2 and Q_3 , slight slurring of QRS_2 and an upright T in the precordial leads.

In the meantime, beginning with the fifth hospital day, the patient began to run a low-grade fever. The lungs were clear. There was slight tenderness at the costovertebral angle. Urinalysis revealed a sediment containing innumerable white cells. A urine culture showed abundant colon bacilli and hemolytic streptococci. A blood culture was negative. On the fourteenth hospital day the patient was put on a course of 0.5 gm. of sulfathiazole every eight hours. He continued to run a temperature of 102°F., but the lungs remained clear, except for a few fine rales at the right base posteriorly. The legs were normal.

A chest plate taken on the twentieth hospital day revealed a large amount of fluid in the posterior

costophrenic angle on the right. On the following day bilateral superficial femoral-vein ligations were done. No clots were found. On the twenty-first hospital day the nonprotein nitrogen was recorded as 38 mg. per 100 cc. The white-cell count was 26,600. The patient complained of pain above the symphysis pubis. The pulse rate was 116, with an occasional dropped beat. The chest showed a few rales, slight dullness and decreased fremitus in the left base posteriorly. The abdomen was somewhat distended. He became weaker, drowsier, went into Cheyne-Stokes respiration and had frequent episodes of vomiting.

On the twenty-sixth hospital day the nonprotein nitrogen was 86 mg. per 100 cc. in spite of an excellent fluid intake and a good urinary output. The electrocardiogram showed a rate of 140, a PR interval of 0.14 second, a sagging ST_1 , an upright T_1 , a sagging ST_2 , an upright T_2 , a low upright T_3 , a wide slurring of QRS_2 , small Q_2 and Q_3 , an upright T in CF_2 , CF_4 and CF_5 , and a sagging ST in CF_4 . A chest plate revealed less fluid in the pleural cavity. There was moderate pitting edema of both feet, in spite of digitalis and restriction of salt. The patient continued to have abdominal distention and episodes of vomiting.

On the thirty-fourth hospital day he exhibited pitting edema of the hands, arms, legs and sacrum. The total protein was 4.3 gm., and the nonprotein nitrogen 52 mg. per 100 cc. Five days later he suddenly complained of severe precordial constriction, without radiation. Physical examination revealed a tachycardia and a scratchy systolic murmur, loudest at the left border of the sternum. The lungs were clear anteriorly and laterally. The patient was not dyspneic or cyanotic. The neck veins were not distended, nor were they pulsating. An electrocardiogram showed a sinus tachycardia of 150, a PR interval of 0.13 second, sagging ST_1 and ST_2 , a low T_1 , an upright T_2 and T_3 , and a sagging ST in CF_4 and CF_5 , with low upright T waves. Six hours after the onset of this attack, on the fortieth hospital day, the patient expired.

DIFFERENTIAL DIAGNOSIS

DR. PAUL D. WHITE: This patient was so old that anything could have been wrong with him. He was not acutely ill at first. He came to the hospital for a urologic check-up.

"The heart was slightly enlarged to the left on percussion," a difficult method of examination in the presence of pulmonary emphysema. X-ray study was certainly in order to determine the true size of the heart.

"The prostate was twice the normal size, nontender, resilient and movable." I do not know whether that rules out malignancy, but I believe that it is evidence against it.

There was some hypertension, largely of the arteriosclerotic type, with relatively low diastolic

pressure, as diastolic hypertensions go. The patient had an extremely high systolic pressure for a time; later it came down. There was a pulse pressure of over 100 mm.

There was hematuria, but not much evidence of severe renal infection at that time. Was more than one culture made? There is a strong suspicion of infection, which may have been renal.

What was the specific gravity of the urine?

DR. BENJAMIN CASTLEMAN: The specific gravity was 1.022; following this it was 1.030, and then 1.012, 1.010 and 1.008.

DR. WHITE: There was evidently good concentration, which is of considerable importance.

DR. CASTLEMAN: Only on admission. After the first week it was in the neighborhood of 1.012 and 1.010.

DR. WHITE: "On the third day the patient suddenly complained of severe, nonradiating, subxiphoid pain accompanied by slight nausea and, two hours later, vomiting." Except for the hypertension, this is where the cardiovascular part of the case comes in.

The split mitral second sound was probably not significant, unless interpreted as a gallop rhythm, which was not at all definite and rather unlikely. If we are looking for trouble below the diaphragm, from the standpoint of an abdominal emergency, nausea and vomiting fit in of course; they are not so frequent with cardiovascular accidents but can occur. Also, one must think of the possibility of pulmonary embolism from phlebitis. The legs were, however, said to be normal. The pulse presumably was definitely felt in the feet.

The blood pressure went up under the stimulus of this pain. That sometimes happens, no matter what the fundamental cause may be; it drops only with great prostration and collapse.

We should not make too much of the electrocardiogram, and yet it may give important clues to explain an acute process. The findings here could have been due to a fresh posterior myocardial infarct, three days old. If a record had been taken on the first or second day, perhaps there would have been more evidence of change in the ST segment if a fresh myocardial infarct had occurred. The tracing is not characteristic of acute cor pulmonale in that there is no S wave in Lead I.

DR. CASTLEMAN: The electrocardiogram was taken forty-eight hours after admission.

DR. WHITE: It was taken reasonably soon after the attack, but the changes would have been more definite in the first twelve hours, especially in the precordial leads. The precordial T wave is high if anything, which helps to rule out an acute cor pulmonale and favors a posterior myocardial infarct. The sagging of the ST segments in Leads CF₄ and CF₆ is also in keeping with that, although it did not last long. The small Q waves are unimpressive.

There was a drop in blood pressure forty-eight hours after the attack.

Another electrocardiogram showed a more pronounced inversion of the T waves in Lead 2 and Lead 3. T₂ is not so deep as before, but there is a greater change in Lead 2, the precordial T waves still being upright, although not so strikingly high. The very height of these T waves makes one think of the possibility of posterior myocardial infarction, for an extremely high T wave is often as significant as an inverted T wave.

There was not a great deal of change in the third electrocardiogram according to the description, mostly a straightening out of the waves; T₂ was flat, and T₃ inverted, although not so deep, again with high T waves in the precordial leads.

How high was the temperature two days after the attack and how high did it go?

DR. CASTLEMAN: It went to 103°F. at one time.

DR. WHITE: That is a fair degree of fever for myocardial infarction alone; in fact, it is higher than one would expect. The lungs were clear, and there was slight tenderness in the costovertebral angle. Urinalysis revealed a sediment containing innumerable white cells. Apparently there was a pyuria. The urine culture showed abundant colon bacilli and streptococci. Much of the fever may have been due to infection in the genitourinary tract.

The patient was put on sulfathiazole, evidently to combat this urinary infection. Probably his physicians thought that the fever was due to infection rather than to the process that was responsible for the substernal pain.

"The legs were normal." They were still looking hard for a source of embolism.

In addition to the information about the chest I should like to know how large the heart was and about the aorta, because in some of these accidents we have to think of dissecting aortic aneurysm, which may involve the renal circulation.

DR. LAURENCE L. ROBBINS: These are the films referred to first. There is a small amount of fluid in the posterior costophrenic angle. The shadow that appears to be within the lungs possibly represents a small area of infarction. In subsequent films, there is rather marked change in the appearance of the vascular shadows in the lung fields. They have increased in size. I cannot be sure of the heart measurements because the film was taken to demonstrate the lung fields rather than the heart. This film gives a fairly accurate idea of the size of the heart. There is no enlargement, but there is evidence of left ventricular hypertrophy.

DR. WHITE: Was that taken before the attack?

DR. ROBBINS: Yes.

DR. WHITE: Despite the systolic hypertension, the heart was not particularly large for a patient of seventy-nine; evidently he supported the systolic

hypertension extremely well, but we do not know how long he had had it.

DR. ROBBINS: There does not appear to be much increase in the size of the heart. In this film, taken later, there is evidence of an increase in pulmonary congestion, and the shadow seen in the previous film is obscured by a high diaphragm.

DR. WHITE: It looks as if there were less fluid.

DR. ROBBINS: I am not certain about the amount of fluid because the film was taken with the patient on his back, and the diaphragm is higher than in the previous films. There might be some fluid.

DR. WHITE: The report says there was "less pleural fluid."

DR. ROBBINS: That is true, but if the fluid gravitated posteriorly in the chest one would see a sharp costophrenic angle and not much fluid.

DR. WHITE: There must have been strong clinical evidence of pulmonary embolism or infarction, since the leg veins were ligated.

The leukocytosis was too high for an infarct of the heart or lung without complications. I think that this indicates that more than one thing was wrong; the genitourinary complication doubtless enters in here.

Is there indication of fluid in the left base?

DR. ROBBINS: No.

DR. WHITE: The patient then became uremic.

The PR interval decreased, characteristic of an increased heart rate, and T₁ came back to a more normal appearance. There is no apparent evidence of a fresh myocardial infarction.

"The total protein was 4.3 gm." That, as well as the renal state, may account for part of the edema.

"He suddenly complained of severe precordial constriction without radiation." Apparently this was not the same as the pain that occurred several weeks previously. It was again precordial, however, although not necessarily substernal; there was constriction. I wonder if he was dyspneic at that time; there is no statement to that effect.

I also wonder whether the pericardial friction rub might have been the result of uremia or of a distended right ventricle and pulmonary artery following pulmonary embolism. There was no evidence of heart failure at that time to explain the fluid in the chest.

In summary, the patient certainly had prostatic hypertrophy and obstruction, quite mild, with retrograde infection of the urinary tract, including pyelitis and terminal uremia. I shall hazard a guess that he had pericarditis resulting from uremia. There was also hypertension, of the systolic type, not causing much cardiac enlargement originally; there was slight left ventricular enlargement, with increase in size of the heart, after the first acute episode, which I shall interpret as posterior myocardial infarction. I shall add to that a diagnosis of terminal pulmonary embolism and infarction —

in these older patients, the more diagnoses the better. Also there was anasarca due to a combination of several factors — renal disease, hypoproteinemia and, perhaps, heart failure.

DR. CONGER WILLIAMS: This patient was on our service last month. I thought that the first episode probably represented myocardial infarction. His veins were tied because there was a suspicion of pulmonary infarction and we thought that it could do no harm. Later many things developed, including terminal uremia. When the final episode started was of no more than academic interest because of other things that had occurred; I thought that the last episode was suggestive of pulmonary embolism, even though the veins had been tied off. Such a thing does happen.

DR. WHITE: The first attack was different from the second?

DR. WILLIAMS: I did not see the patient in the last attack, but as it was described to me it sounded as if it were due to pulmonary embolism.

DR. HOWARD B. SPRAGUE: Do you think that he had a pulmonary embolus that arose in the right heart following the basal infarct?

DR. WHITE: Such a condition is rare.

DR. SPRAGUE: I know it, but I recently had a case.

DR. WHITE: It is possible, but I should not make that diagnosis.

CLINICAL DIAGNOSES

Benign prostatic hypertrophy.
Chronic pyelonephritis.
Uremia.
Old pulmonary infarct with bilateral vein ligations.
Recent myocardial infarction?

DR. WHITE'S DIAGNOSES

Prostatic hypertrophy and obstruction.
Pyelitis.
Uremia.
Pericarditis, uremic.
Hypertension, with slight cardiac hypertrophy.
Posterior myocardial infarction.
Hypoproteinemia.
Anasarca.
Pulmonary embolism and infarction, terminal.

ANATOMICAL DIAGNOSES

Myocardial infarction: left ventricle and posterior part of septum.
Interstitial myocarditis and generalized perivascular cellular infiltration (sulfonamide idiosyncrasy).
Cardiac hypertrophy, hypertensive type.
Pyelonephritis, acute and chronic.
Prostatic abscesses.

Adenocarcinoma of prostate.
Cystitis.
Hydrothorax, bilateral.
(Uremia.)

PATHOLOGICAL DISCUSSION

DR. CASTLEMAN: The autopsy showed an enlarged heart, weighing 420 gm., of the hypertensive

the neoplasm around nerves, and no evidence of metastasis anywhere in the body.

Microscopic sections of the heart showed, first, the obvious infarct of almost a month's duration. Sections away from the infarct and corresponding to the location of the pinpoint grayish-red areas observed grossly showed an interstitial myocarditis. There was a cellular infiltration, consisting mostly of eosinophils and monocytes, in the interstitial

FIGURE 1. Photomicrograph of Section of Heart Muscle.

type, the hypertrophy being left ventricular. In the right coronary artery, 9 cm. from its origin, we found an occluding recent organizing thrombus, the age of which would fit in with the time of the attack that he had had on the third hospital day. The circumflex and descending branches of the left coronary artery were markedly sclerotic, but there was no evidence of occlusion.

The myocardial infarction was limited to the posterior wall of the left ventricle, although there were some tiny grayish-red areas in other parts of the heart that we could not explain. There were no infarcts in the lung, and no evidence of pulmonary emboli.

There was 500 cc. of fluid in each chest cavity, but none in the abdomen.

Both kidneys were markedly enlarged and swollen, and we thought that grossly they suggested a pyelonephritis. The bladder showed a mild cystitis. The prostate was enlarged to twice the normal size, showing considerable necrosis and infection. In one area there was a small but definite adenocarcinoma. There was no evidence of extension of

tissues, especially around the blood vessels (Fig. 1). These findings are quite similar to those of interstitial myocarditis due to sulfonamides, first observed by French and Weller.¹ Similar perivascular infiltrations were found in the lungs (Fig. 2) and in one section of smooth muscle. I believe that these changes followed the sulfonamide therapy, apparently a hypersensitivity reaction. Perhaps this is the early stage of the frank periarteritis that has been described by Rich.² There were similar areas in the kidney, but one cannot be sure that they were due to sulfonamides. The patient had a severe pyelonephritis, and they can be explained on that basis. In a case of severe sulfonamide nephrosis, which we discussed here a year ago,³ the myocardium showed exactly the same picture—eosinophilic, lymphocytic and monocytic infiltration in the interstitial tissues and around the vessels.

It is quite possible that some of the changes in the electrocardiogram may have been due to these lesions. Dr. Bernard Maisel, who worked in our laboratory a year or so ago on sulfonamide intoxications, has just told us about a patient who

received sulfonamides prophylactically before an intestinal resection for carcinoma and who after the operation developed signs of cardiac failure with queer electrocardiographic changes; at autopsy the myocardium showed severe interstitial myocarditis.

DR. WHITE: In this case, some of the later changes did not fit in with the myocardial infarct, although

DR. CASTLEMAN: Yes.

DR. WHITE: Hence, congestive heart failure might have accounted for some of the fluid in the chest.

CASE 30442

PRESENTATION OF CASE

A forty-three-year-old railroad worker was admitted to the hospital with pain in the region of the left costovertebral angle.

The patient was apparently in good health until two years prior to admission, at which time he had an attack of severe stabbing pain in the region of the left costovertebral angle, radiating to the left groin. Similar attacks, each lasting a few seconds, recurred at intervals of once or twice a week. He developed urinary frequency of about six to seven times daily and twice nightly. He also had pain and discomfort in the right upper quadrant, as well as abdominal distention at times. There was no jaundice, nausea or vomiting. One month prior

to admission the attacks increased in frequency and severity, occurring daily. At no time did he notice hematuria or pyuria, nor did he pass any gravel. He had lost 14 pounds over a period of six months. Because of his symptoms he visited the out-patient department of another hospital, where urograms were taken. These showed a huge left hydronephrosis with multiple calculi in the pelvis and calyces and no function. The right kidney was poorly visualized but was apparently normal in outline and pattern.

Except for the fact that the patient had been consuming four to five quarts of alcohol weekly over a period of five to six years, the past and family histories were noncontributory.

Physical examination revealed a well-developed man who appeared chronically ill. The heart and

lungs were normal. The left kidney was readily palpable, and left costovertebral angle tenderness was present. The spleen could not be felt.

The blood pressure was 130 systolic, 70 diastolic. The temperature, pulse and respirations were normal.

Examination of the blood revealed a red-cell count of 3,350,000, with 60 per cent hemoglobin, and a white-cell count of 12,500. A voided specimen of urine had a specific gravity of 1.010, with a ++ test for albumin and many red and white cells in the sediment. The blood nonprotein nitrogen was 26 mg., the sugar 123 mg., the calcium 10.7 mg., and the phosphorus 4.4 mg. per 100 cc. The alkaline phosphatase was 2.4 units per 100 cc. The prothrombin time was 14 seconds (normal, 18 to 20 seconds). The serum protein was 6.9 gm. per 100 cc., with an albumin-globulin ratio of 1.4. A urine culture showed a few colonies of *Staphylococcus albus* and diphtheroids.

An intravenous pyelogram revealed numerous areas of calcification overlying the left kidney, which was not well visualized. No dye appeared on the left over a period of twenty minutes. The outline of the right kidney was normal, and the dye appeared promptly.

On the fifth hospital day an operation was performed.

DIFFERENTIAL DIAGNOSIS

DR. FLETCHER H. COLBY: The significant points in the history of this patient are the intermittent attacks of left costovertebral pain over a two-year period, which radiated to the groin at the outset. There was moderate frequency of urination, but no gross hematuria; and no stones were passed. Prior to admission the frequency increased and there was considerable loss of weight. Urograms were said to have been taken at another hospital that demonstrated a huge left hydronephrosis with multiple calculi; since this kidney undoubtedly had no function at that time, a retrograde pyelogram must have been done to visualize the renal pelvis.

The history suggests, of course, left renal colic, with stones as the likeliest cause. Such symptoms, however, may be due to other conditions, such as renal tumor, usually associated with the passage of blood clot, and various obstructive congenital lesions. Gastrointestinal symptoms are frequently produced by a fairly advanced lesion of the kidney, because of pressure on neighboring organs from a large renal mass or possibly reflexly through the sympathetic nervous system.

On physical examination the left kidney was sufficiently enlarged to be readily felt and there was left costovertebral angle tenderness. Moderate anemia was present. The urine was low in specific gravity and contained both blood and pus. The blood chemical findings, with normal calcium, phosphorus and protein determinations, appear to eliminate parathyroid disease. *Staph. albus* and diphtheroids

were found in the cultured urine. The diphtheroids are contaminants, but the staphylococcus is probably significant since some strains of this organism invade the urinary tract and are capable of separating urea, thus favoring stone formation by the strongly alkaline urine that is produced.

At x-ray examination the many areas of calcification are typical of stones scattered throughout a dilated, badly damaged, functionless left kidney. There is no good reason to suspect tumor from the evidence we have, although there is no method of eliminating this possibility. Tuberculosis is seldom associated with such extensive stone formation. One of the congenital abnormalities may have been the background for the renal damage and stone formation, but again we have no definite evidence of this. The operation performed on the fifth day was presumably a left nephrectomy for a calculus pyonephrosis. The appearance of the stones by x-ray suggests that they were composed of calcium phosphate.

CLINICAL DIAGNOSES

Nephrolithiasis.

Pyonephrosis.

DR. COLBY'S DIAGNOSES

Nephrolithiasis.

Pyonephrosis.

ANATOMICAL DIAGNOSES

Nephrolithiasis.

Pyonephrosis.

Carcinoma in situ and epidermoid carcinoma of renal pelvis, multiple.

PATHOLOGICAL DISCUSSION

DR. BENJAMIN CASTLEMAN: This case was used in these exercises to illustrate one of the extremely rare conditions occurring with renal stones. As Dr. Colby predicted this patient did have a large pyonephrotic fluctuant kidney, with obliteration of most of the parenchyma by the dilated calyces (Fig. 1). There were several large stones within the pelvis and calyces. The unusual finding was the presence of several grayish-white, slightly raised, granular areas about 2 cm. in diameter on the mucosal surface of the pelvis and some of the calyces. In a few places these apparent tumors extended into the parenchyma. In other areas the mucosa was merely roughened.

Microscopic examination revealed all stages in the development of epidermoid carcinoma. The slightly roughened areas showed a marked atypicality and anaplasia of the epithelium but no evidence of invasion — a condition that we call "carcinoma in situ" (Fig. 2). Other areas showed early invasion with extensive keratinization — a Grade I epidermoid carcinoma (Fig. 3). In the grossly invading foci the carcinoma was a bit less differentiated and might be classified Grade II or III.

Although it cannot be proved, the presence of

multiple foci of carcinoma in all stages of development dated the neoplasm. It therefore seems reasonable

FIGURE 1. *Photograph of the Bisected Kidney.*
The arrow points to one of the granular areas mentioned in the text.

ment associated with multiple renal stones suggests that the chronic irritation of the calculi led to the

that the continued irritation of the stones and the infection had a great deal to do with the formation

FIGURE 2. *Photomicrograph of a Section of the Kidney.*
This area shows carcinoma in situ of the pelvic epithelium.

FIGURE 3. *Photomicrograph of a Section of the Kidney.*
This area shows epidermoid carcinoma of the renal pelvis.

formation of the neoplasms.

DR. COLBY: The curious appearance of the kidney certainly suggests that the stone formation ante-

of the carcinoma. There have been a sufficient number of similar cases reported in the literature to support this point of view.

UNITED WAR FUND

FROM now until November 23 the Greater Boston United War Fund will be holding its campaign to raise \$7,650,000 for home-front and war-related appeals.

On meeting the home-front needs depends the physical and social health of the community. Two hundred and sixty-seven hospitals, clinics, dispensaries and youth and social services are affiliated with the Fund. Physicians need not be told of the work these services do; indeed, physicians give generously of their time and energy to serve the health of the community, and day after day see for themselves the needs of those whom they and these agencies serve.

In a world seething with hate and killing, our own community is only a small part of our responsibility. Every contribution to the Greater Boston United War Fund is also a direct gift to some homesick soldier or weary sailor overseas. We give to our men in uniform when we give to the USO, the United Seamen's Service, the War Prisoners Aid and the American Field Service. The needs of these men will not be immediately decreased when the European phase of the war ends, for the repatriation of prisoners will take a long time, large armies of occupation must be kept, and the problem of morale will increase. Then, too, our efforts in the Pacific will be increased, and these services must be ready for still larger tasks on the other side of the world.

Not less important are those who have suffered far more and far longer than any of us. United Nations Relief goes to sixteen war-ravaged countries, whose occupants have borne the brunt of the fight.

For our own neighbors, our fighting men and our brave allies, give and "Show That You Care."

NEED FOR REORGANIZATION

ALTHOUGH, by and large, during the last two years the people of the United States have not truly suffered from the lack of medical, nursing and hospital care, a number of situations have arisen that have already resulted in the lowering of standards of which this country had just reason to be proud. Furthermore, it seems likely that many, if not all, of these blunders might have been avoided if a broader and more knowledgeable attitude had been taken regarding the demands for medical and nursing personnel by the Army and Navy, particularly the former.

The men in the armed forces deserve the best of medical care, — and this they are undoubtedly receiving, — but unlike butter, the physician and the nurse are commodities that the civilians, the majority of whom are contributing in one way or another to the war effort, cannot do without. To cut down below a certain level, as well as to accelerate medical education, creates conditions that eventually undermine the health of the population. Already there is a shortage of hospital beds that

might be catastrophic in the event of a nationwide epidemic, and the average number of days of hospitalization has been prolonged, both of which are largely due to a depleted medical and nursing personnel. Medical-school graduates, to say nothing of faculty members, are tired and confused by three years of accelerated teaching, and hospitals obviously cannot give adequate practical training during a nine-month rotating internship or under the 9-9-9 plan. Finally, deferment has been denied to premedical students at a time when the number enrolled under the Army and Navy training programs has been drastically cut; this can only result in a diminution in the number of properly qualified students.

The educational aspect is forcefully brought to the attention of the medical profession by Dr. Evarts A. Graham in an editorial published in the August issue of *Surgery, Gynecology and Obstetrics*, which reads as follows:

The medical schools and civilian teaching hospitals of this country are engaged in the education of medical officers for the armed services. . . . That the efforts of the medical schools and teaching hospitals have been successful is attested by the extravagant praise accorded, especially, to the surgeons in the Army and Navy for the astonishingly high percentage of wounded men returned to active duty. . . .

The surgeons who are responsible for this splendid record are men who not only had the benefit of four years in a medical school following a good premedical training in the colleges but in addition spent several years in special training in our civilian teaching hospitals. Many also have fulfilled the requirements for fellowship in the American College of Surgeons and for certification by the American Board of Surgery. . . . The Army has recognized the importance of [such] qualification . . . by giving a certain amount of preferential consideration to the members of the College and particularly to those who hold certificates of the American Board.

This splendid plan, however, . . . has been scrapped by the War and Navy Departments. Laymen . . . have dictated what may be given in a premedical course, have streamlined the medical course itself and have practically destroyed the resident system of training. Many medical officers will now enter the army to serve in battalion aid stations and in other places demanding a knowledge of surgery whose maximum graduate hospital experience has been nine months of a rotating intern service with perhaps only two months in surgery. Is this the kind of medical officer the armed forces want? Pity the wounded if it is!

Let us imagine a group of surgeons with the authority to prescribe the education of line officers, be they Army or Navy. Would they wreck West Point and Annapolis? Would they reduce their faculties by 40 or 50 per cent at the same time that they increase the number of the students? Would they reduce the period of training of artillery

officers or submarine commanders to an amount which could not possibly make them efficient? It seems unlikely that they would. . . .

Is the medical officer of less value than the line officer? The General Staff may think so, but we know full well that a modern army could not function at all without its medical department. . . .

Although the Surgeon General . . . is no longer a member of the General Staff, the Army must appreciate the value of the medical officers because it wants so many of them even if they are only half-baked. In fact much of the present difficulty arises because of the large number wanted. At the outbreak of the present war we were told that the army needed 6.5 medical officers for each 1000 men in the Army. . . .

The demand for so large a number of medical officers is the fundamental cause of the disruption of the prewar efficient plan for their education. . . . Shall we send our men into battle with Civil War muskets if the supply of modern arms is deficient? Of course not. Anybody can see how ridiculous and murderous that would be. But perhaps only doctors themselves can appreciate how murderous a half-baked medical officer can be.

Is it necessary that this large number of medical officers be provided? If it is then everybody will be glad to make the best of it. The armies of other countries have not been furnished with anything like so high a proportion of medical officers. The British, the Australian, and the Canadian armies, for example, get along with a proportion only a little more than half of what is felt necessary by our armed forces; and the quality of the work done is excellent. . . . Is not this demand for so many medical officers an unjustifiable extravagance for which there is no demonstrated need?

These remarks have been directed at the evil effects upon the medical officers themselves caused by the disruption of the only plan for developing properly trained surgeons which has ever been found to work. A similar editorial could be written on the disaster to the civilian population. Are we to go backward a quarter of a century and to surrender to our two great allies the enviable position in medicine which this country occupied before the war? The British Commonwealth and Russia have not found it necessary to disrupt their medical education to anything like the extent which we have been forced to do. As a result we may find ourselves a poor third in medicine in the postwar world. Is it necessary? I know of no convincing evidence that it is. But nothing will be done to remedy the situation unless the medical profession itself, the only body capable of understanding how a medical officer should be educated, speaks its mind loud enough for Congress and the President to hear. Reduce the 6.5 ratio to a reasonable one and much of the basis for the wrecking of our medical education will disappear. The 9-9-9 plan will not train surgeons and will not provide competent surgical officers. Still less will the nine months' rotating internship. That plan should be scrapped and in its place a reasonable program for the training of medical officers should be substituted immediately after a proper inventory of the real needs of the armed services has been made. . . .

Dr. Graham's plea for "a reasonable program for the education of medical officers . . . after a proper inventory of the real needs of the armed

forces" seems justified, and it is likely that this would result in the correction of the other faults. As he suggests, and as Dr. Loyal Davis claims in an editorial published in the September issue of *Surgery, Gynecology and Obstetrics*, the chief source of trouble, at least so far as the Army is concerned, stems from the fact that the Medical Department, a relatively independent unit prior to February, 1918, is part of the Army Service Forces; the Surgeon General and the medical officers in combat zones are under the control of the General Staff, which includes no medical officer, with the result that all matters of policy must be approved or presented for higher consideration by line officers. Due credit should be given to the Directing Board of the Procurement and Assignment Service for being able to maintain the minimum required medical personnel on the home front, thus giving to the Army every physician who could be spared; on the other hand, this board's power is limited, and proper co-operation can be hoped for only if the Medical Department is completely reorganized. The Surgeon General of the Navy is not handicapped by such limitations, and as Dr. Davis points out, the Surgeon General of the Russian Army is directly responsible only to the Chief of Staff. A similar arrangement should obtain in the Army of the United States, and the medical profession should so inform their representatives in Washington, with the hope that the latter will act with courage and force.

DEATH

HALTON — Edward P. Halton, M.D., of Holyoke, died October 18. He was in his sixty-third year.

Dr. Halton received his degree from Yale University School of Medicine, New Haven, in 1905. He was a member of the American Medical Association.

His widow, two sons and a sister survive.

NOTICES

AMERICAN FEDERATION FOR CLINICAL RESEARCH

An all-day meeting of the Eastern Section of the American Federation for Clinical Research is being planned for December 9. Investigators desiring to read papers on clinical research should submit an abstract of not over 200 words to Dr. Orville Bailey, Harvard Medical School, 25 Shattuck Street, Boston 15, before November 15. The meeting will be held in Boston and will be open to members of the medical profession.

BOSTON SOCIETY OF BIOLOGISTS

A meeting of the Boston Society of Biologists will be held in the Main Lecture Room of the Harvard Biological Laboratories on Wednesday, November 15, at 8 p.m.

PROGRAM

Milkman's Disease. Dr. F. Albright.

On the Enzymatic Splitting of Lecithin in Animal Organisms. Drs. G. Schmidt and S. J. Thannhauser.

Werner's Syndrome (Progeria of the Adult) and Rothmund's Syndrome. Dr. S. J. Thannhauser.

FORUM ON ALLERGY

The seventh annual Forum on Allergy will be held in the Hotel William Penn, Pittsburgh, Pennsylvania, on Saturday and Sunday, January 20 and 21, 1945. This is a meeting to which all physicians are most welcome, and where they are offered an opportunity to bring themselves up to date in this rapidly advancing branch of medicine by two days of intensive postgraduate instruction. For instance, the twelve study groups, any two of which are open to him, are so divided that those dealing with ophthalmology and otolaryngology, pediatrics, internal medicine, dermatology and allergy run consecutively. In addition, the study groups are arranged on the basis of previous registration. In this way, as soon as the registrations are completed, the registrant is expected to write the group leader and tell him just what questions he wants brought up in the discussion. Attention is also called to the fact that during these two days almost every type of instructional method is employed — special lectures by outstanding authorities, study groups, pictures, demonstrations, symposiums and panel discussions. Further information may be obtained from Jonathan Forman, M.D., 956 Bryden Road, Columbus 5, Ohio.

HODGKIN'S DISEASE*

III. Symptoms and Course

HENRY JACKSON, JR., M.D.,† AND FREDERIC PARKER, JR., M.D.‡

BOSTON

IN THE present installment of this series of papers on Hodgkin's disease, the initial symptoms of the three types of that condition will be discussed, and the general course of the disease will be briefly illustrated. In a subsequent issue, the symptoms and signs arising from involvement of certain organs will be discussed in more detail.

Hodgkin's Paragranuloma

Hodgkin's paragranuloma is a comparatively benign condition the onset of which is virtually always heralded solely by painless lymphadenopathy, usually in the cervical region (Table 1).

Systemic symptoms are absent at first, and the patient appears to be in good health. Occasionally the disease is discovered on routine physical examination.

According to our experience, approximately 20 per cent of the cases progress after months or years to Hodgkin's granuloma. It must be em-

No symptoms	2

phasized that the insidiousness of the onset in no way precludes this development and as we have already pointed out, those cases that progress cannot, even by the most careful histologic study, be distinguished in their incipency from those that do not.

The course of Hodgkin's paragranuloma is extremely variable. In certain cases, there develop

signs or symptoms suggesting a transition to Hodgkin's granuloma and death ensues within a short time; in others, many months or several years elapse before the development of Hodgkin's granuloma; in still others, the condition remains quiescent for many years, and death may be due to some intercurrent disease or the patient may survive and remain in excellent health for many years. In these last cases, however, there is always the possibility that the disease will once more become active or that Hodgkin's granuloma will develop. This has been seen to happen as long as nineteen years after the initial lesion was discovered. Involvement of the mediastinal lymph nodes may take place; this does not necessarily imply that Hodgkin's granuloma is developing, but enlargement of the spleen has, in our experience, been an ominous sign. The onset of systemic symptoms, such as fever, weakness, anorexia or loss of weight almost always indicates that a transition to the granulomatous form has taken place. There is no characteristic blood picture, although one occasionally finds an increased percentage of polymorphonuclear neutrophils. There is no anemia.

The following case histories illustrate the course of the disease.

CASE 1. J. H. (Pv. 5-42), a 40-year-old man, was first seen on May 20, 1942. Six years previously, he had noted a lump in the left groin. This did not bother him, and it remained approximately the same size until September, 1941, when it began to increase in size. It was therefore removed, and showed the typical features of Hodgkin's paragranuloma. There was also a small lymph node in the right axilla. Otherwise the physical examination was within normal limits. The blood picture was normal. A moderate amount of x-ray therapy was given to the left groin and to the node in the axilla.

The patient remained well until September, 1942, when he noticed some pain in the right upper quadrant of the abdomen and increasing weakness necessitating his resting when he returned home from work. At that time, there were a few small lymph nodes in both sides of the neck and in each groin. The spleen was palpable 4 cm. below the costal margin. Otherwise the physical examination revealed no notable abnormalities. The red-cell count was normal, but the white-cell count had risen to 20,000, with 80 per cent polymorphonuclear neutrophils. A moderate amount of x-ray therapy was given to each quadrant of the abdomen,

and any system may appear to be primarily implicated.

Initial Symptoms

As will be seen from Table 2, painless enlargement of cervical lymph nodes is by far the most frequent initial symptom of the disease. They may be situated in the anterior or posterior triangles or under the sternomastoid muscle. Not infrequently an upper respiratory infection has immediately preceded the enlargement, which may

TABLE 2. Initial Symptoms of Hodgkin's Granuloma (213 cases).

SYMPTOMS	NO. OF CASES
Enlarged cervical lymph nodes	111
Pain (usually in abdomen or back)	26
Weakness	14
Enlarged axillary lymph nodes	14
Enlarged inguinal lymph nodes, anorexia, cough	9 each
Dyspnea, loss of weight, abdominal mass	7 each
Chills	5
Itching	4
Vomiting	3
Weakness of legs, amenorrhea, fever, hematemesis, edema of legs, hemoptysis	2 each
Melenia, sternal mass, dysuria, enlargement of tonsil, sore throat, skin nodules, constipation, deafness, dysphagia, cyanosis, sweats	1 each

diminish greatly with the subsequent subsidence of the acute process, so that the physician is not unnaturally led to suppose that he is dealing with a simple inflammatory lymphadenopathy and treats the case accordingly. In other cases, a varying though moderate degree of lymphadenopathy is present over a considerable period of time, and increases after a respiratory infection to such a degree as to demand medical attention. This sequence of events is seen in the following case.

CASE 5. R. E. S. (P. H. 13671), a 24-year-old woman, was admitted to the hospital on March 10, 1938. In the spring of 1933, she had noticed enlarged, painless, nontender lymph nodes in the left side of the neck. There was no associated sore throat or upper respiratory infection, nor were there any constitutional symptoms. For the next 5 years, the nodes fluctuated in size for no ascertainable reason, varying from 1 to 2 cm. in diameter. Occasionally they disappeared entirely. There were no constitutional symptoms. In January, 1938, the patient developed an acute upper respiratory infection of considerable severity, and immediately thereafter the cervical nodes increased rapidly in size.

On entry to the hospital, physical examination revealed an obese, healthy-looking woman. In the anterior and posterior triangles of the left side of the neck and beneath the sternomastoid muscle were several firm, nontender lymph nodes varying from 2 to 5 cm. in diameter. There was no other lymphadenopathy, but the upper part of the mediastinal shadow was definitely widened in the x-ray film. Aside from a moderate elevation of the white-cell count and an increase of the percentage of polymorphonuclear neutrophils in the peripheral blood, the laboratory findings were within normal limits. A biopsy of one of the cervical lymph nodes showed Hodgkin's granuloma. Appropriate x-ray therapy was directed to the neck and mediastinum, with complete disappearance of all masses. The patient was still in excellent condition and gaining weight when last seen in May, 1944.

In a adult, the persistence of notably enlarged lymph nodes for a considerable period of time after an acute upper respiratory infection or the development of persistent masses in the neck after minor

infections must be regarded with suspicion, particularly if the posterior triangle or the supraclavicular region is involved. Painless enlargement of lymph nodes in the neck unassociated with obvious infection always calls for careful investigation, and it has been our experience that without biopsy an accurate and definitive diagnosis cannot be made.

The enlarged lymph nodes are usually nontender, and rarely cause pain unless they press on adjacent nerves or are adjacent to obvious septic foci. Later, pain due to lymphadenopathy is more frequent, particularly when the lymph nodes are in the groin or the axilla. The overlying skin is usually normal in appearance, and the nodes are seldom fixed to the surrounding structures, although they may become immobile by the very fact that they fill the entire neck and impinge on contiguous fixed structures. It should be borne in mind, however, that as a result of poulticing or other self-medication, the overlying skin may become reddened and that an associated infection in the nasopharynx may cause the nodes to be temporarily painful and tender, even in the early stages of the disease. In consistence, the nodes are usually firm and rubbery, occasionally soft and rarely hard. They never have the stony feel so suggestive of metastatic carcinoma, unless they have already been subjected to heavy radiation. On rare occasions, the nodes are extremely soft and even fluctuant.

In our experience, there is no predilection for one or another side of the neck, and in the majority of cases, the involvement is bilateral when the patient is first seen, although almost invariably one side is involved to a far greater extent than the other, and only rarely does one see the evenly distributed bilateral nodes of uniform size and relatively soft consistence so often found in lymphatic leukemia. No particular part of the cervical region appears to be most frequently involved. It is wise, however, to search with special care for nodes beneath the sternomastoid muscles and in the region immediately above the clavicles. Enlarged nodes are not infrequently found in the submaxillary and submental regions, but those confined sharply to such regions are rarely due to Hodgkin's granuloma and are likelier to be secondary to some obscure infection of the floor of the mouth. This fact may be of some practical value in diagnosis.

Enlarged lymph nodes elsewhere, as in the axilla, groin and inguinal regions, have in general the same characteristics as those in the neck, although they are more prone to be painful and only rarely fluctuate in size, probably owing to the fact that they are less likely to be influenced by adjacent infectious processes.

Pain is the next most frequent initial complaint, but it should be emphasized that early in the course of Hodgkin's granuloma this symptom is compar-

and the patient improved considerably and gained weight. Nevertheless, a month later he again began to feel poorly and noted an elevation of temperature each afternoon. He was readmitted to the hospital and was found to have generalized lymphadenopathy. The red-cell count had fallen to 3,900,000, and he was therefore given several transfusions of whole blood. The x-ray examination of the chest showed numerous small patches of consolidation the nature of which was somewhat uncertain, although it was believed that since several of them were definitely nodular, the lesions probably represented metastases from a newly developed Hodgkin's granuloma. This suspicion seemed to be substantiated by the fact that the pulmonary lesions cleared up after an x-ray dosage of 1600 r had been given to the chest. X-ray therapy was then directed to the peripheral lymph nodes. The patient's general condition, however, did not improve. The fever continued, and he began to have drenching night sweats.

In January, 1943, generalized lymphadenopathy appeared. The red-cell count gradually fell to 1,600,000 and the hemoglobin to 35 per cent. Following further x-ray therapy and several blood transfusions, the patient improved somewhat and the fever subsided. After a very short time, however, the weakness and fever returned and the patient grew steadily worse until his death on March 20, 1943.

Autopsy showed widespread involvement by typical Hodgkin's granuloma.

This case illustrates the rapidity with which Hodgkin's paraganuloma occasionally develops into Hodgkin's granuloma.

CASE 2. F. S. (Pv. 8-29), a 45-year-old man, in 1927 first noticed a few small, painless lymph nodes beneath the right sternomastoid muscle. In 1929, a node was removed that on subsequent review showed the typical picture of Hodgkin's paraganuloma. There were no general symptoms at that time, the patient felt perfectly well, and no other abnormalities were noted on physical examination. X-ray treatment was given to the right cervical area, and the patient remained entirely asymptomatic for 6 years, — March, 1935, — when enlarged lymph nodes were noted in the left side of the neck. These were excised and showed a histologic picture suggesting a transition between Hodgkin's paraganuloma and Hodgkin's granuloma. X-ray therapy was again given, the lymph nodes subsided, and the patient remained asymptomatic until March, 1938. At that time, he developed a moderate degree of anorexia and definite bitemporal hemianopsia. He became weak, listless and apathetic. Physical examination was essentially normal except that the visual fields were notably contracted and the spleen could be felt 3 cm. below the costal margin. He was given an x-ray dosage of 600 r at 250 kv. to each side of the head, and his symptoms entirely subsided.

In June, 1938, the anorexia returned. In addition, the patient, a highly intelligent man of robust stature, noticed that all food tasted unusually sweet. With the passage of time, this sense of sweetness became so great that the patient, although co-operative, was unable to eat anything except the most highly spiced foods, and but little of these. A large mediastinal mass was visualized by x-ray, and a moderate degree of hypochromic anemia had developed. The white-cell count, normal at all previous examinations, had risen to 17,000, with 85 per cent polymorphonuclear neutrophils. The patient was given an x-ray dosage of 1000 r at 100 kv. to the head, with some temporary relief from the sensation of sweetness. The mediastinal mass completely disappeared after 800 r to the anterior part of the chest. The anorexia, however, became increasingly severe, and for the next 6 months the patient subsisted almost entirely on peptonized milk and hard-boiled eggs, to each of which he added, in order that they might not "taste too sweet," astounding amounts of cayenne pepper. There was no suggestion of hysteria, and all those who examined him were convinced that the symptoms had an organic basis, although no one was able to localize the lesion. He became extremely emaciated, as might well be expected, and died on April 27, 1939, 10 years after the onset of his condition.

Autopsy failed to reveal, even after the most careful and scrupulous examination, any lesion, either gross or microscopic, in the nervous system to account for the hemianopsia or the abnormality of taste. A few enlarged lymph nodes,

particularly about the head of the pancreas and in the retroperitoneal area, showed the histologic changes of Hodgkin's granuloma. The most prominent lesion seen was an extreme degree of amyloidosis, chiefly in the lymph nodes, kidneys, liver and spleen. Although Hodgkin's granuloma was found at autopsy, the lesions were not extensive enough to cause death, which must be attributed to inanition following extreme anorexia, the cause of which remains entirely obscure.

CASE 3. J. H. (B. C. H. 408240), a 17-year-old man, was admitted to the hospital on September 22, 1920, with the sole complaint of painless lymph nodes in the right side of the neck. The past history had been uneventful. In 1915, he noted a few small lymph nodes in the right side of the neck. These increased slowly in size, and in 1917 one was removed for diagnosis. No record of this biopsy had been preserved. In August, 1920, the patient complained of an increasing sense of constriction in the neck and upper thorax and noticed that the lymph nodes in the cervical region had increased greatly in size.

Physical examination at that time revealed no abnormalities except for the presence of a large number of firm, elastic nodes in the right side of the neck, extending from the mastoid region to the supraclavicular area. A radical dissection was done and all the apparently diseased tissue was removed. Examination of the lymph nodes showed the typical picture of what we now recognize as Hodgkin's paraganuloma. Unfortunately, the patient was told by one of his friends that he would die in 6 months, and as a respite from this gloomy outlook, he had recourse to hard liquor in large amounts. At the end of a year, he was still alive but was unable to forego alcohol. He remained symptom-free, however, until September, 1939, when he again noticed nodes above the clavicle and a sense of tightness in the neck. Physical examination showed many firm nodes above the right clavicle; these appeared to extend into the thoracic cage. A biopsy showed that the process had progressed into a typical Hodgkin's granuloma. A large mediastinal mass developed, and in spite of x-ray therapy, the patient died in 1942, 27 years after the initial lymphadenopathy and 3 years after the known transition of the Hodgkin's paraganuloma into Hodgkin's granuloma.

CASE 4. L. C. (Pv. 2-36), a 36-year-old woman, was admitted to the hospital in April, 1936. In 1910, at the age of 10 years, enlarged lymph nodes had appeared in the right side of the neck. These had been removed at another hospital and showed the histologic picture of what we now call Hodgkin's paraganuloma. The patient remained entirely well until 1917, when the nodes recurred. They were removed and again showed precisely the same features as they had in 1910.

No further signs or symptoms occurred until February, 1936, when masses were once more noted in the right side of the neck. Physical examination showed no abnormalities except that beneath the upper third of the right sternomastoid muscle were a group of firm, freely movable nodes. These were excised as completely as possible, and they too showed the histologic features of Hodgkin's paraganuloma. Thus there had been no appreciable change in the histologic picture since 1910. At present, 34 years after the initial lymphadenopathy, the patient is free of signs and symptoms.

This case illustrates the benign character of the process when it remains unaltered. Why one patient rapidly develops Hodgkin's granuloma whereas another remains in comparatively good health is entirely obscure.

HODGKIN'S GRANULOMA

It is of the greatest importance to recognize clearly the extraordinarily protean character of the symptomatology of Hodgkin's granuloma. It is true that in the majority of cases painless enlargement of one or more cervical lymph nodes first attracts the patient's attention to his condition, yet so diverse are the symptoms and so varied are the signs that almost any disease may be simulated

General Course

In the great majority of cases, Hodgkin's granuloma progresses inexorably to a fatal termination, but the course is extremely variable, and aside from the broadest generalities, it is impossible in any given case to predict what changes will take place or precisely when they will occur. Virtually any organ or tissue in the body may be involved, and the clinical course of the disease depends in large measure on the extent and rapidity of the spread as well as on which organs are involved. In one case, the pathologic changes may become so widespread and so all-inclusive that no organ can properly fulfill its function, and death ensues from a sort of general attrition; in another, sudden death may occur at a time when the patient seems to be in comparatively good health.

The disease does not advance in an even, orderly fashion. Remissions occasionally occur in a quite unpredictable manner, and patients who have seemed to be failing under the best of treatment may unaccountably respond most favorably to what is regarded as a final therapeutic gesture. On the other hand, it is not unusual to see a patient who has been doing especially well for many months or even years become rapidly worse and die within a few weeks.

In view of these facts, it seems profitless to attempt any working classification of the various clinical types that are met with in practice. It is true that in one case, the process may be confined largely to the mediastinum, in another to the spleen and in still another to the gastrointestinal tract. In some cases anemia is a marked feature, in others high fever. A patient may be seen in whom loss of weight and strength has been, from the onset, a striking feature; again, a patient may be able to continue hard physical labor until the end is but a short way off. In this sense, there are clinical types, yet each case is a law unto itself, and the disease can be treated more intelligently if this fact is constantly borne in mind.

Hodgkin's granuloma only rarely progresses sharply into Hodgkin's sarcoma, a far more malignant form of the disease. Such transformation is far less frequent than the comparable progression of Hodgkin's paraganuloma into Hodgkin's granuloma.

The following cases illustrate the varied course of Hodgkin's granuloma.

CASE 8. C. C. (C. H. 167400), a 6-year-old girl, was admitted to the hospital on January 1, 1933. The past history was irrelevant. She had always seemed healthy. Approximately 3 weeks before entry, the parents had noticed enlarged lymph nodes in each side of her neck. These increased rapidly in size, and a week later she developed a severe cough, associated with some hoarseness and a moderate elevation of temperature. For a week before entry, she had had marked anorexia.

Physical examination on admission revealed a well-developed and well-nourished girl suffering from a marked degree of dyspnea. In the anterior posterior triangle of both sides of the neck were numerous rubbery lymph nodes

1 to 4 cm. in diameter. They were not attached to the skin or to the underlying tissues. The throat appeared normal. Examination otherwise revealed nothing abnormal except for a pronounced widening of the mediastinal dullness, a finding that was confirmed by x-ray examination. The temperature was 102°F., the pulse 140, and the respirations 30. The red-cell count was 3,800,000 and the white-cell count 13,400, with 72 per cent polymorphonuclear neutrophils, 2 per cent myelocytes, 20 per cent lymphocytes and 6 per cent monocytes. A biopsy of one of the cervical lymph nodes showed the picture of Hodgkin's granuloma. The patient's dyspnea increased, the temperature rose to 104°F., and she died of respiratory failure less than a month from the apparent onset of her condition.

CASE 9. K. A. D. (H.H.36-542), a 20-year-old man, was admitted to the hospital on May 25, 1936. A year before entry, he had had a mild upper respiratory infection, following which there had appeared an enlarged lymph node in the right side of the neck. There was no impairment of general health. The node was neither tender nor painful, but it persisted after the subsidence of the respiratory infection. Eight months later, the patient's family noticed that he was becoming pale. For several weeks before admission, he ran a septic type of temperature and had many drenching night sweats. Shortly thereafter, there appeared edema of the ankles and scrotum, and coincidentally both the hearing and vision began to fail.

Physical examination on entry showed an emaciated man lying apathetically in bed. His vision was markedly impaired, and he could not read the largest newspaper type. The left eye showed a moderate degree of enophthalmos and was deviated downward and inward. The right fundus oculi showed several patches of exudate similar to that seen in chronic nephritis, and in addition a large area of chorioretinitis on the temporal side of the disk. In neither ear could the patient hear the tick of a watch. Both nostrils were filled with clotted blood, and the lips were parched, cracked and bleeding. In the right side of the neck from the angle of the jaw to the supraclavicular space were many firm, discrete lymph nodes averaging 2 cm. in diameter. Recently there had been excised from this region a lymph node showing the typical picture of Hodgkin's granuloma. In each groin were large numbers of firm, tender lymph nodes, and many similar ones could be felt deep in the pelvis above the pelvic brim. The heart was normal in size. Signs of moderate ascites were present, but neither the liver nor the spleen could be felt. There was marked edema of both legs and of the scrotum and penis. The red-cell count was 2,130,000, the hemoglobin 50 per cent (Sahli), and the white-cell count 2000, with a normal differential count. The platelets were greatly diminished. The urine contained a slight trace of albumin and a few red cells. The temperature was 103°F., and the pulse 130.

Since the disease was obviously widespread, involving the central nervous system, ears, eyes, chest, abdomen, pelvis, bone marrow and peripheral lymph nodes and since his condition seemed desperate, it was decided to give several blood transfusions before instituting x-ray therapy. In addition, he was put on a high-caloric diet.

Between May 26 and June 11, three blood transfusions totaling 1600 cc. were given, with the result that the hemoglobin rose to 50 per cent and the red-cell count to 3,500,000. During the interval, his general condition remained essentially unaltered but, interestingly enough, the hearing improved sufficiently so that the patient could hear a watch tick in both ears and could understand normal conversation. The eyesight also improved, although not to the same extent. The patient's condition appeared to warrant the institution of x-ray therapy, and inasmuch as the most marked lymph-node involvement was in the pelvis, radiation was directed to that area, and from June 11 to 15 he received 275 r of high-voltage x-rays. He suffered no untoward reaction to this small amount of radiation, so that between June 15 and 22 he was given 1000 r to the abdomen. The temperature remained elevated, the physical examination was essentially unaltered, and the general condition seemed, if anything, rather worse. The patient became jaundiced and even during the day was somewhat drowsy. He took no notice of his surroundings, and it was difficult to arouse him from his almost constant lethargy. The red-cell count had fallen to 1,940,000 and the hemoglobin to 32 per cent.

The outlook was certainly not bright, and all therapeutic measures to date appeared to have been unavailing. In view

atively rare. In Hodgkin's sarcoma and reticulum-cell sarcoma, on the other hand, pain is often an early and almost constantly a late symptom. The most frequent sites of pain are the abdomen and the back. In the former, it is in most cases caused by retroperitoneal lymph nodes, and it is perhaps surprising that this symptom is not found oftener, for many authors have emphasized the frequency with which the retroperitoneal nodes are involved, and our own experience is in agreement with this finding.

Only rarely is pain due to invasion of one of the abdominal viscera as in the following case.

CASE 6. E. M. (B. C. H. 559573), a 47-year-old man, was admitted to the hospital on May 10, 1923, with a chief complaint of upper abdominal pain. Thirteen years previously, he had been operated on for a "perforated gastric ulcer." No data were available as to the nature of this ulcer. Convalescence, however, had been uneventful, and the patient remained symptom-free until January, 1923, at which time he began to suffer from a burning epigastric pain occurring shortly after meals and lasting approximately an hour. There was no nausea or vomiting. During the next 3 months, he lost about 15 pounds, and 3 days before entry to the hospital he vomited "a cupful" of bright-red blood.

Physical examination on admission showed evidence of an old healed tuberculous process in the apex of the right lung and a moderate degree of anemia. The abdomen showed no tenderness, spasm or masses. X-ray examination revealed an extensive irregularity and mottling of the cardia and media of the stomach, and a diagnosis of carcinoma was made. The red-cell count was 3,280,000, the hemoglobin 55 per cent (Sahli) and the white-cell count 16,000, with 86 per cent polymorphonuclear neutrophils, 10 per cent lymphocytes and 4 per cent monocytes. The stools gave a strongly positive guaiac test. The patient failed rapidly, and in spite of two blood transfusions, the red-cell count fell to 2,800,000 and the hemoglobin to 40 per cent. Persistent vomiting developed, and he died 3 weeks after entry.

Autopsy showed extensive Hodgkin's granuloma of the stomach, with extension into the liver and pancreas and involvement of the gastric and retroperitoneal lymph nodes.

Rarely abdominal pain is caused by great enlargement of the spleen.

Pain in the back, usually in the lower thoracic or lumbar region, may be due to a variety of causes. In obscure cases, one is often forced to the conclusion that enlarged lymph nodes are pressing on one or more spinal nerves. Not infrequently back pain is due to direct involvement of the bodies of the vertebrae or to granulomatous lesions in the dura or epidural space, and it is of the greatest importance to recognize the fact that lesions of the spine may be present for several months before they can be visualized on x-ray films. Pain due to involvement of bone is well illustrated by the following case.

CASE 7. B. B. (H. H. 36-543), a 34-year-old woman, was admitted to the hospital on May 25, 1936. In February, 1933, she began to complain of fleeting pains of no great severity in the low lumbar region. The pain was made worse by exercise, and was not constant. A careful physical examination at that time by her physician revealed only slight tenderness and spasm of the muscles in the right lumbosacral region. The symptoms continued with exacerbations and remissions, in spite of baking, massage and simple orthopedic measures, until May, 1935. The pain then became constant, was much worse at night and radiated from the lumbar region bilaterally to the lower abdomen. Nine months later,

in February, 1936, the patient began to lose weight and to complain of anorexia, nausea and occasional attacks of vomiting.

Except for evident loss of weight, — she had lost 25 pounds, — the physical examination showed only a few discrete, firm, bean-sized lymph nodes in each side of the neck. The red-cell count was 3,890,000, the hemoglobin 63 per cent (Sahli), and the white-cell count 33,000, with 90 per cent polymorphonuclear neutrophils and 10 per cent lymphocytes. X-ray films of the spine and pelvis showed extensive hyperplastic changes in the bodies of the 3rd, 4th and 5th lumbar vertebrae and in the left portion of the pelvis consistent with those of Hodgkin's granuloma. A biopsy of a small node in the right side of the neck showed the typical picture of that condition. X-ray therapy relieved the back pain for a few months, but splenomegaly, hepatomegaly and a left-sided pleural effusion developed, and the patient died in early October, 1937, 19 months after the bone lesion had been demonstrated by x-ray.

When the change from Hodgkin's paraganuloma to Hodgkin's granuloma actually first developed is of course, problematical, but this case illustrates the importance of careful x-ray studies in patients with obscure and recalcitrant back pain, and the wisdom of searching for enlarged lymph nodes that may give a clue as to the true condition.

Pain in the chest, shoulder, groin, leg or axilla is occasionally encountered as an initial symptom. Usually under such circumstances unequivocal evidence of Hodgkin's granuloma is present.

Generalized weakness is not infrequently the first symptom, and in the absence of obvious lymphadenopathy or splenomegaly may be a most difficult one to evaluate. A careful search should be made for enlarged lymph nodes and abdominal masses, and the finding of an elevated basal metabolic rate or an elevated white-cell count with an increased percentage of polymorphonuclear neutrophils may be of some diagnostic significance.

Not infrequently, symptoms referable to the gastrointestinal tract first attract the patient's attention. If there has been melena or hematemesis, some intrinsic lesion is usually discovered at autopsy. Other symptoms, such as anorexia and nausea, can only rarely be traced to such an intrinsic lesion.

Finally, there are a considerable number of the most varied initial signs and symptoms, such as anorexia, edema of the legs, dyspnea, loss of weight, abdominal masses, cough, generalized itching, amenorrhea, hemoptysis, persistent sore throat, vomiting, hematemesis, dysphagia, melena and deafness. One can only bear in mind that Hodgkin's granuloma may first manifest itself in such ways and endeavor to prove whether it is present.

In a considerable number of cases there is initially a combination of several symptoms, in which event the condition is usually already well advanced. Yet it should be pointed out that this fact by no means necessarily militates against relatively successful therapy.

It is thus clear that Hodgkin's granuloma is usually first manifest by painless cervical lymphadenopathy, but that its initial stage may be marked by the most diverse symptoms and signs.

symptom, but the enlarged lymph nodes seldom atrophy in size as they frequently do in Hodgkin's granuloma. Weakness, dyspnea, cough and vomiting may be seen early. Rapid loss of weight is much more frequent than in Hodgkin's granuloma and may be the outstanding feature of the disease. Thus, pain was an initial complaint in over 50 per cent of our cases of Hodgkin's sarcoma, whereas it was present initially in only 12 per cent of patients suffering from Hodgkin's granuloma. Symptoms suggesting involvement of internal organs were noted at onset in 75 per cent, whereas they were present in less than 30 per cent of the patients suffering from Hodgkin's granuloma.

On the average, patients sought medical advice within five months of the apparent onset of their disease, yet even after this short interval the initial complaints had been almost invariably supplemented by many others, and during the course of the disease, still further symptoms reflect the rapidly

TABLE 4. *Symptoms During Course of Hodgkin's Sarcoma (32 cases).*

SYMPTOMS	NO OF CASES
Fatigue	28
Loss of weight	26

Chills	3

invasive and malignant character of the tumor. The disease runs an insidiously rapid course even though the initial response to x-ray therapy may have appeared to be good. Fatigue and rapid loss of weight are frequent. The majority of patients develop pain referable to the organs or tissues involved, and often there is cough due to the frequent involvement of the lung. Fever, on the other hand, is rare; by contrast its frequency in Hodgkin's granuloma is well known. Symptoms and signs referable to the various organs will be discussed in more detail in a subsequent paper. In general, it may be said that Hodgkin's sarcoma runs the course of a highly malignant neoplasm.

The following cases illustrate the course of the disease.

CASE 13. G. P. (B. C. H. 92408), a 37-year-old man, entered the hospital in October, 1929, because he had had epigastric distress for the previous 2 months. The pain was constant, radiated to the umbilicus and was greatly aggravated by the ingestion of food. There had been no vomiting, hematemesis, melena or jaundice. There were no other symptoms of importance, and the past history was irrelevant.

On physical examination, a freely movable mass the size of an orange was felt in the epigastrium. In each axilla and in each side of the neck were several firm lymph nodes 4 to 5 cm. in diameter. The spleen was felt 3 cm. below the costal margin. There were no other abnormalities of note. The temperature was normal. The red-cell count was 4,000,000,

the hemoglobin 92 per cent (Sahli), and the white-cell count 25,000, with 75 per cent polymorphonuclear neutrophils, 23 per cent lymphocytes and 2 per cent monocytes. Biopsy of one of the axillary lymph nodes showed Hodgkin's sarcoma.

Six hundred roentgens of x-ray therapy was given to the abdomen and to the nodes in the axilla and neck. Two weeks later, neither the epigastric mass nor the superficial lymph nodes could be felt. The response to radiation was dramatically satisfactory, and for 6 months the patient felt perfectly well. In April, 1930, however, he returned to the clinic and enlarged lymph nodes were found in the cervical, axillary, inguinal and popliteal regions. No abdominal mass could be felt. Six hundred roentgens of x-ray therapy were given to each involved area, but there was little if any subsequent improvement in the patient's condition, in spite of this dosage and subsequent additional x-ray therapy. Indeed, he soon began to complain once more of severe epigastric pain, especially after meals, and of vomiting, weakness and marked loss of weight.

In August, 1930, the patient was readmitted. At that time, there were in each side of the neck and in each axilla firm lymph nodes 10 cm. in diameter that were neither fixed nor tender. The spleen was found to be 5 cm. below the costal margin, and the liver was barely palpable on deep inspiration. The red-cell count had fallen to 1,230,000 and the hemoglobin to 35 per cent (Sahli). The white-cell count was 2550, with 90 per cent polymorphonuclear neutrophils, 8 per cent monocytes and 1 per cent lymphocytes. The urine examination was negative.

From then until his death 3 weeks later, the patient ran an irregular fever to 100°F. and the pulse gradually rose from 90 to 130. The right leg became edematous, presumably from pressure of lymph nodes in the inguinal region, and in the right parietal bone of the skull there developed a palpable defect. X-ray examination showed a large erosion of the skull in this region. Many petechiae appeared in the skin of the chest and abdomen and in the mucous membranes of the mouth. The patient failed steadily and died on August 20, 1930, just a year after the appearance of his first symptom.

Autopsy showed Hodgkin's sarcoma involving the retroperitoneal, mesenteric, mediastinal, cervical, axillary and inguinal lymph nodes, as well as the spleen, liver, kidneys, pancreas, adrenal glands, duodenum, ileum, colon, lumbar vertebrae and skull.

CASE 14. P. C. (H. H. 24-806), a 49-year-old man, was first seen in June, 1924, at which time he complained of pain in the throat. Two and a half months before entry, he had had frequent sore throats. Otherwise, the history was noncontributory.

On examination, the right tonsillar fossa was found to be occupied by an ulcerated tumor 6 cm. in diameter. It was not bleeding. A moderately large, firm lymph node was palpable beneath the angle of the right mandible. No other abnormalities were noted on physical examination. The patient was instructed to return 1 week later for biopsy and further study, but he did not reappear until September, 3 months afterward. In the interim, his sore throat had recurred at irregular intervals without any specific treatment. Examination showed in the right tonsillar region a tumor that extended high up into the nasopharynx. No lymph nodes were felt in the neck. There were no other abnormalities. The red-cell count was 5,800,000, the hemoglobin 95 per cent (Sahli), and the white-cell count 5600 with 55 per cent polymorphonuclear neutrophils, 37 per cent lymphocytes, 5 per cent eosinophils and 3 per cent monocytes. A biopsy was performed, and the lymph node removed showed all the characteristics of what we now call Hodgkin's sarcoma.

In November, 1924, eight radium seeds of 1 m.c. each were implanted in the tumor, and within 6 weeks it had completely disappeared. The patient remained asymptomatic for 6 months.

In June, 1925, he again developed a sore throat, and the left tonsil was found to be enlarged and ulcerated. Implantation of radium seeds (four of 1.5 m.c. each and two of 1 m.c. each) resulted in rapid shrinkage in the size of the tumor. In September of the same year, a mass of lymph nodes was palpable in the left side of the neck. One so-called "suberythema dose" of high-voltage x-ray was given over this area. For the next 16 months, the patient felt perfectly well and did not report to the follow-up clinic.

of the falling red-cell count, the patient, between July 1 and 10, was given transfusions totaling 3000 cc. of blood, with a resultant rise of the red-cell count to 3,480,000. By that time, the temperature had come down to normal, the hearing was normal, and the eyesight, although still poor, was much improved. The patient was allowed up and around the wards within the limits of his strength. His appetite, which on admission had been practically nil, was now ravenous. His general condition improved daily, and he rapidly gained both strength and weight. The emaciated, apathetic boy first seen became an optimistic young man. The lymph nodes in all areas became much smaller. The ocular manifestations improved, with the exception of the retinal changes, which remained unaltered. The peripheral edema and ascites disappeared. On July 20, the patient was given another blood transfusion of 500 cc., and on July 25 he walked out of the hospital to return to his home.

In August of the same year, the cervical lymph nodes returned and increased rapidly in size, but after administration of 600 r to each side of the neck they completely disappeared, and the patient seemed in excellent condition and was able once more to return to work as a laborer.

He continued to work at hard manual labor until December, 1936, when he again became weak and complained of anorexia, nausea and vomiting and ringing in the ears. There were many firm lymph nodes in each side of the neck. The mediastinal shadow was increased to the right, and the spleen was palpable 3 cm. below the costal margin. The temperature was 103°F., the pulse 130, and the respirations 35. Examination of the blood showed a red-cell count of 1,570,000 and a white-cell count of 4000. The patient was given three blood transfusions of 500 cc. each and 75 r of spray x-ray therapy, both anteriorly and posteriorly. Following this, his general condition improved greatly, the lymph nodes and spleen disappeared, and he was once more able to resume his normal activities. In May, 1937, however, he was again troubled with anorexia and vomiting, and the temperature rose to 102°F. The spleen was barely palpable on inspiration. Many fine rales appeared at the apex of the right lung. There was no return of the lymph-node enlargement, but the patient failed steadily, and again became partially blind and deaf. The temperature remained constantly between 101 and 103°F., the red-cell count fell to 2,630,000, and the patient died on August 25, 1937, which was 2 years and 3 months after the date of his first symptom.

CASE 10. E. M. (P. H. 1887), a 52-year-old man, was in excellent health until May, 1929, when he noticed a small lump in the left axilla. It was neither painful nor tender, and he had no other complaints. Physical examination showed a firm mass 6 cm. in diameter high in the left axilla, a pea-sized lymph node above the left clavicle and a similar one in the left epitrochlear region. Otherwise, the examination showed no abnormalities. The red-cell and white-cell counts were within normal limits, and x-ray films of the chest failed to show any widening of the mediastinal shadow. The axillary and epitrochlear nodes were excised, and each showed the typical histologic picture of Hodgkin's granuloma. The patient was given 900 r to the left axilla and 600 r to the left epitrochlear region.

There have been no recurrences, and the patient has remained well to date, 15 years from his first symptom.

CASE 11. J. P. (P. H. 2757), a 48-year-old, Italian laborer, noted in August, 1930, ease of fatigue, anorexia, night sweats and a mass in the left axilla; he continued at his work, however. Three months later there appeared an enlarged lymph node in the right axilla. This was removed and showed the usual picture of Hodgkin's granuloma. He was admitted to the hospital on December 6, 1930.

Physical examination revealed a firm, nontender lymph node 4 cm. in diameter in the left axilla and several similar ones in the left supraclavicular area. The spleen was palpable 3 cm. below the costal margin. An x-ray film of the chest was normal, and it was specifically noted that there was no evidence of bone involvement. The general condition was good. The red-cell count was 3,850,000, the hemoglobin 60 per cent (Sahli), and the white-cell count 11,400, with 79 per cent polymorphonuclear neutrophils, 1 per cent eosinophils, 15 per cent lymphocytes and 5 per cent monocytes. Six hundred r was given to the left side of the neck, with rapid disappearance of the nodes. Three weeks later, however, the patient noticed a raised, tender swelling 6 cm.

in diameter over the lower part of the sternum. X-ray film showed an extensive irregular mottling and destruction of the gladiolus, and on physical examination there was a hard, tender swelling rising 2 cm. above the general level of the sternum and 10 cm. in diameter. The patient was given 600 r to the left side of the neck, each axilla and the spleen at 1000 r over the sternal mass. The nodes disappeared following this treatment. The sternal mass became much smaller but did not disappear.

During the intervening years, he has received 2400 r to the involved area. The last x-ray films still showed the bone destruction, but when last seen in the spring of 1944, 1 years after his first symptoms, the patient was feeling perfectly well and was capable of doing reasonably hard manual labor.

Cases 10 and 11 attest the value of early treatment, and show that Hodgkin's granuloma is not always so rapidly fatal as is generally believed.

CASE 12. A.P. (H. H. 17-646), a 10-year-old boy, in 1911 noticed a plum-sized mass in the right side of the neck. It was excised and showed the histologic features of Hodgkin's granuloma. Physical examination revealed no other abnormalities, and both the past and family histories were noncontributory. The peripheral blood picture was normal. At intervals during the next 8 months, 8200 m. c. h. of radium was given at the site of the lesion and 800 m. c. h. to the mediastinum.

For the next 15 years, the patient remained entirely well except that from time to time minute nodes were noted under the anterior part of the jaw. This minor lymphadenopathy appeared to be due to oral sepsis.

In 1930, at a routine checkup, there was found a mass the size of a small plum in the submaxillary region on the left side. This was removed and again showed the picture of Hodgkin's granuloma. An indeterminate amount of x-ray (probably about 600 r) was directed at the left side of the neck. The patient thereafter remained free of all signs of symptoms up to December, 1941, when he moved to another city and was lost sight of.

Whether this result can properly be regarded as a cure in the true sense of the word is perhaps debatable. That the results were excellent no one can deny, for the patient was alive and well nearly 30 years after the initial lymphadenopathy.

HODGKIN'S SARCOMA

Pain is the most frequent initial symptom of Hodgkin's sarcoma (Table 3). It is most frequent in the abdomen, is usually unrelated to meals,

TABLE 3 Initial Symptoms of Hodgkin's Sarcoma (32 cases)

SYMPTOMS	No. OF CASES
Pain	17
Abdomen	9
Lymph nodes	4
Chest	2
Throat	2
Painless enlargement of lymph nodes	8
Weakness	5
Loss of weight	5
Dyspnea	4
Cough	3
Vomiting	2
Sore throat	2
Anorexia	2

and is occasionally accompanied, even early in the disease, by loss of weight. Pain may, of course, occur elsewhere, and it is to be particularly noted that the superficial lymph nodes are often painful. This is rarely the case in Hodgkin's granuloma. Painless lymphadenopathy may be the sole initial

my or Navy his sex habits have been quite well established, and that regardless of all efforts made in the field of sex education many of these young men will be sexually promiscuous. For such, venereal prophylaxis is advocated. There are those who on moral grounds argue against venereal prophylaxis. Their stand is due in part to the fact that some prophylactics are also contraceptives. There are aspects that a single, simple, clean, nonirritating prophylactic that is not contraceptive but is efficient against both syphilis and gonorrhea will soon be available. If so, it is hoped that much of the present opposition will disappear.

During World War I, the attempt was made to control venereal disease by punitive measures. Men were punished for failing to take a prophylactic after exposure and also for acquiring a venereal disease. Consequently, a soldier's only chance of escaping punishment if he became infected with gonorrhea or syphilis was to conceal his illness. This was frequently done with more or less success by his going to some nonreputable agency for treatment. Often this resulted in his avoiding punishment, but it was notoriously ineffective from the standpoint of curing the infection and protecting public health. Punitive measures have failed in every venereal-disease-control program in which they have been utilized. The modern public-health attitude is to look on gonorrhea and syphilis as communicable diseases and not as crimes, and to consider a venereal infection as a public-health menace until it is brought under control. The most efficient way to get such infections under control is to offer the best possible diagnostic and therapeutic services without the necessity of the patient's losing all his or her self-respect, and to eliminate all punitive measures. The Army has adopted this intelligent attitude. A soldier who now acquires a venereal disease is punished only if he conceals it. He does lose pay for time spent in a hospital for a venereal infection but by authorizing the treatment of gonorrhea on a duty status the Army has made it possible for a man so treated to avoid forfeiture of pay. This is unquestionably good medical and sound public-health practice.

At the beginning of the present emergency, divisions of venereal-disease control were established in the offices of the surgeons general of the Army and Navy. It had long been recognized that if no one is specifically charged with the duty of controlling venereal disease there will be no control, but when certain persons are designated for such a specific duty much progress is made. This has been noted in many of the state health departments, in which during the last several years divisions of venereal-disease control have been established. Both services are to be congratulated for taking such an important step in connection with one of their major problems, and also for their wise selection of officers to head these branches. These well-trained, highly efficient officers are responsible for their respective control programs, which are based on the best scientific

experience so far as it is compatible with the difficulties of military administration. It is obvious that in a theater of operation a venereal-disease-control program must be a compromise between what is the best and what is practicable. It is an old American custom for armchair strategists to point out errors of commission or omission in the conduct of wars. An impartial observer familiar with all the facts could find little if anything to criticize in the way the venereal-disease program is being run in the armed forces, both at home and abroad.

A large group of medical officers who have been given intensive courses of instruction in venereal-disease control are now stationed in the several service commands, naval districts and large military units, where they are functioning as venereal-disease (V.D.) control officers. That the venereal-disease sections are doing an excellent job is revealed by the present situation as contrasted with the past. Turner and Brumfield¹ state that during the last century rates of over 150 per 1000 per annum were not unusual in the Army. The annual rate for 1939 was 29.6 per 1000 per annum, which was the lowest recorded until that time. There are indications that the present rate is even lower. In 1940 the days lost as the result of venereal disease were 1278 per 1000 men, and in 1943 this figure dropped to 400. Although these figures indicate a decided improvement, there were nevertheless 2,824,000 hospital-bed days from January, 1942, to September, 1943, due to venereal disease, which means that there is still too much morbidity.

Every serviceman known to have gonorrhea or syphilis is interviewed by a medical officer who attempts to get from him the identity of his recent sex contacts. The information obtained is sent to the state department of health, whereupon trained epidemiologists attempt to locate the woman and to persuade her to go to some medical agency for an examination. This may be a private physician or a clinic. It is discouraging to note that, of the women who go to a private physician for diagnosis in Massachusetts, infection is detected in 53.2 per cent, whereas 71.6 per cent of those examined in clinics are found to be infected. These figures are statistically significant. It is known that many of the women who go to a private physician and are said to be noninfectious have been and continue to be identified by enlisted men as their only recent sex contacts. This suggests that some physicians are not willing to utilize the most efficient diagnostic procedures available. Some physicians have admitted that laboratory studies were not done because the woman did not have clinical evidence of infection. Experience during recent years indicates that many women found to be infected with gonorrhea do not show any of the so-called "typical" signs or symptoms of the disease.

Cultures, although far from perfect, are more efficient than any other known method in detecting

In February, 1927, he returned complaining of recent difficulty in breathing, severe headache and a painful mass in the neck. The pharynx appeared normal, but there was a bloody discharge from the almost completely obstructed nasal passage and a hard, walnut-sized lymph node was found in the right side of the neck. An x-ray film of the chest disclosed enlarged mediastinal lymph nodes. High-voltage x-ray therapy was given to the thorax and neck, without any beneficial effect. The development of deafness, diplopia, right unilateral exophthalmos and finally blindness bore witness to the rapid extension of the neoplasm within the skull. The patient died on April 22, 1927, just 3 years after the first symptom.

Autopsy showed a tumor having the histologic features of the condition now referred to as Hodgkin's sarcoma, which was primary in the right tonsil. There was direct extension to the nasopharynx, sphenoidal sinus, right orbit, right temporal bone, pituitary gland and dura mater. Metastases were found in the pancreas and mesenteric lymph nodes.

CASE 15. J. C. (B. C. H. 974896), a 53-year-old woman, was admitted to the hospital on February 14, 1940, with the chief complaint of "gas on the stomach." The past history was entirely noncontributory. For 3 weeks prior to admission, she had noted that during or immediately after meals she felt "bloated," and there had been almost constant nausea. Anorexia had been extreme, and she had grown progressively weaker.

Physical examination revealed several enlarged, rubbery lymph nodes behind the left sternomastoid muscle. Otherwise, there were no notable abnormalities. Gastric analysis showed absence of free hydrochloric acid, and both the gastric contents and the stools gave a strongly positive guaiac reaction. The red-cell count was 5,100,000, the hemoglobin 71 per cent (Sahli) and the hematocrit 37. The white-cell count was 4600, with 68 per cent polymorphonuclear neutrophils, 10 per cent lymphocytes, 17 per cent monocytes, 4

per cent eosinophils and 1 per cent basophils. The temperature, pulse and respirations were normal.

A gastrointestinal series showed no abnormality in the esophagus, but x-ray examination of the stomach revealed a large fungating tumor arising near the cardia. The mass appeared to encroach on the esophagus but caused no obstruction. The remainder of the gastrointestinal tract appeared normal.

The patient became increasingly short of breath and failed rapidly. The lymph nodes in the neck increased greatly in size, and within a week there developed signs of obstruction of the superior vena cava. Fluid accumulated in the left pleural cavity, and 2 months after admission 900 cc. of bloody fluid was removed. Anorexia became extreme, and the patient died on April 19, a scant 3 months after the first symptoms.

Autopsy showed extensive involvement of the greater curvature of the stomach by Hodgkin's sarcoma, with direct invasion of the pancreas and diaphragm, massive serous effusion in the left pleural cavity and extensive involvement of the abdominal lymph nodes.

* * *

From the case histories and the discussion above, it should be clear that in broad terms Hodgkin's paraganuloma is a comparatively benign condition occasionally progressing to Hodgkin's granuloma; that Hodgkin's granuloma is characterized by the most protean manifestations, is usually, though by no means invariably, fatal within a few years, and on rare occasions progresses to Hodgkin's sarcoma; and finally that Hodgkin's sarcoma behaves as a highly malignant, comparatively localized tumor rapidly resulting in death.

VENEREAL DISEASE AS A WAR INJURY*

OSCAR F. COX, M.D.†

BROOKLINE, MASSACHUSETTS

VICTORY in the shortest possible time is our objective. It is the duty of every one of us to do all in his power to prevent delay. Morbidity in the armed forces, or among the men and women who produce the munitions without which the fighting men cannot hope to achieve victory, is something that concerns us as physicians. Every case of morbidity among these people is a war injury, and among such cases venereal diseases are high on the list.

During all previous wars in which this country has engaged, the incidence of gonorrhea, and to a lesser extent that of syphilis, has been appalling. The cause of high venereal-disease rates during wartime is largely psychologic. When large numbers of people become affected by war hysteria, a marked increase in sexual promiscuity results. Since promiscuity is the cause of the wide dissemination of the venereal diseases, the less there is in a given group the lower will be the venereal-disease rate. If it were possible to have everyone adhere to the one-man, one-woman ideal, venereal disease would disappear in one generation. Although there appears to be no

hope of attaining such an ideal in the near future, it is a goal toward which society should constantly strive.

Before Pearl Harbor it was my privilege to talk with many high-ranking line officers, most of whom had a sound understanding of sex and venereal disease. An occasional officer, however, expressed himself paradoxically to the effect that a man could not be a good soldier unless he occasionally had sexual relations, but that any soldier so stupid as to acquire a venereal disease was not wanted in his command. As physicians we should like to know what diagnostic procedures the soldier was expected to utilize in order to eliminate the possibility of venereal disease.

Fortunately, the Army and Navy are officially committed to the repression of prostitution. Continence is their number-one approach to the venereal-disease problem. It is the duty of commanding officers to see that all men in their commands are given data about sex and venereal disease, particularly the fact that continence is compatible with manhood and good health. The armed forces are, however, realistic in that they concede that by the time a man is old enough to be inducted into the

†Associate professor of medicine, Boston University School of Medicine; director, Division of Genitoinfectious Diseases, Massachusetts Memorial Hospitals.

No one yet knows whether penicillin is capable of curing syphilis. Certain facts are known, and these are most encouraging. Mahoney's³ first 4 cases, which were given an eight-day course of treatment, have been observed for eleven months. All became skin-field negative within a few hours after the first injection. This was followed by an early healing of the lesions and a steady drop in the syphilitic reagin titer, and all the serologic tests became negative. One of these patients has yet had a clinical or a serologic relapse. The spinal fluid in each case is negative. Whether or not they have been cured of syphilis will not be known until they have been observed for a considerable period. Since Mahoney's original work many other patients with early syphilis have been treated with penicillin, and although the observation periods have not been sufficiently long to justify final conclusions, their progress to date more or less parallels Mahoney's results.

The modern trend in the arsenotherapy of syphilis is to concentrate the curative dose in the shortest possible time. The highly publicized five-day treatment stimulated some much needed investigations. The old standard eighteen-month continuous alternating system, although efficient and relatively safe, was unsatisfactory in that throughout the country probably not more than 15 per cent of those with early syphilis received what was considered to be adequate treatment. Shortening the time of treatment may be expected to increase this figure.

Many modifications of the five-day treatment have been advocated; one-day drug and fever, five-day intravenous drip, ten-day multiple injection, and thirty-day, eight-week, ten-week and twelve-week schedules, all designed to give a curative dose of Mapharsen. It is known that a given

amount of Mapharsen has a definite therapeutic index, whether given in five days or several weeks, but that the shorter the time the greater is the risk of toxicity.

All systems of arsenotherapy cause a certain amount of morbidity, most of which is mild but nevertheless undesirable. No cases of morbidity as the result of penicillin therapy have been reported. This fact seems to be of great importance to the armed forces. If it should be established that penicillin is as efficient as the arsenicals, a great advance in medicine will have been made.

* * *

Although gonorrhea and syphilis are still important causes of morbidity in the armed forces, they are relatively less so than in any previous mobilization. This is due first to the fact that the Army and Navy both have capable organizations whose specific job it is to control venereal disease, and second to the immediate utilization by the services of the almost unbelievable advances that are being made in the therapy of these diseases.

Morbidity from venereal disease can be further reduced. This would mean fewer noneffectives in the armed services and on the home front. It is unquestionably our duty to bring this about at this critical time when it is imperative that we do our utmost to eliminate everything that may impede victory.

SURGICAL EXPERIENCES WITH THE WOUNDED OF THE BUNA CAMPAIGN*

COLONEL AUGUSTUS THORNDIKE, M.C., A.U.S.

MAJOR General Norman T. Kirk, the Surgeon General of the Army, has stated that out of every 100 wounded in battle in this war 97 may be expected to survive. This is truly a glowing tribute to modern military medicine. All those who have husbands, sons or brothers in combat may take heart and gain great hope that their nearest of kin, if wounded, have a very good chance of returning home. It is my duty to report any thoughts and any facts that we with overseas experience in military service can pass on, even though they concern a minor fraction of the total experience in caring for the sick and wounded of the Army.

The title confines my remarks to an action with the enemy — the first participated in by our Army ground forces that occupied a period of approx-

imately twelve weeks from early November, 1942 — the Buna Campaign in New Guinea. On reaching the continental United States it seemed strange that little general interest had been gained concerning the Southwest Pacific theater. To be sure, the action to be described was not one participated in by large bodies of troops, but it was an important engagement, and particularly so in respect to the soldiers who were taking part in it. Those decorated with the Purple Heart will never forget that experience — they carry scars that have a meaning. The nearest of kin of those killed will remember this engagement. Good surgery near the line of combat saved many lives. Native litter bearers performed heroic service in evacuating the sick and wounded on hand-hewn litters. Up to this date the Fifth Air Force has evacuated more than

gonococci in women. No woman who admits a sexual contact and who has been identified as a possible source of a known infection should be diagnosed as not infected, no matter how normal she may appear on inspection, without at least one negative culture. The Massachusetts Department of Public Health will shortly announce a new regulation to the effect that whenever a woman is alleged to have been exposed to, or to have been, the source of a gonococcal infection the department shall require that there be one or more negative cultures of material taken from the urethra and cervical canal before it will accept a report that the person is free from infection. As a matter of fact, it would be a wise public-health measure to give a five-day course of sulfathiazole to all women who admit a recent exposure to a known case of gonococcal infection, regardless of negative laboratory findings. If this were done, many infections now overlooked would be cured, and this would probably lower the rate of infection in the services.

There have been no advances in therapy that are more electrifying than the newer methods of treating gonorrhea and syphilis. With the introduction of the sulfonamides from two thirds to three fourths of gonococcal infections were cured within two to five days, whereas previously cure had taken from two to five months. Today more than 95 per cent of all gonococcal infections, sulfonamide-resistant and sulfonamide-susceptible, can be cured with penicillin in eight to ten hours.

Frequently there is a considerable lag between the announcement of a new discovery by laboratory and clinical investigators and its adoption by the medical profession. There has been no hesitancy by the armed forces in adopting newer treatment methods for venereal disease. Existing methods have been altered immediately as soon as clinical trial has demonstrated something more efficient. For this the services are to be commended. Inasmuch as the armed forces are said to have an adequate supply of penicillin, it may be that in the near future all gonococcal infections in the services will be treated with this highly efficient agent.

Until a few months ago servicemen with gonococcal infections were given a course of chemotherapy, and if this did not result in cure they were given a second course after an interval of two or three days. Those who were not cured by the second course were, so far as facilities permitted, sent to a general hospital for fever therapy. Fever therapy has now been discarded in favor of penicillin, and it was recently announced that military personnel with gonococcal infections would be given but one course of sulfathiazole, and that if this failed to cure they would be given penicillin without further delay. It may appear fantastic, but it is nevertheless conceivable that the Army could provide facilities in infirmaries where men with gonococcal infections could report at six o'clock in the afternoon, go to

bed and be given an injection of penicillin every two to three hours during the night, and be discharged to duty at 6 or 7 o'clock the next morning, cured of their infections. This would mean that the loss of man power due to gonorrhea would be almost negligible.

Between March 13 and April 30 of this year, 7 patients with sulfonamide-resistant gonococcal infections—60 men and 17 women—were treated with penicillin in the Out-Patient Department of the Massachusetts Memorial Hospitals. Each received a total dosage of 90,000 Oxford units given in divided doses from 9 a.m. to 5 p.m. on the first day and one injection on the morning of the second day. Positive cultures were obtained from every case just previous to the beginning of treatment. Cultures were done at two-hour intervals during the first day and daily thereafter for three days, and then once a week for three weeks. In only 2 cases were positive cultures obtained after the first injection. In one the culture was positive two hours after beginning treatment but all subsequent cultures were negative. In the second case a positive culture was obtained twenty-four hours after beginning treatment but all cultures on succeeding days were negative. Further experiments are being conducted for the purpose of working out a system of therapy whereby it will not be necessary for patients to give up an entire day to the treatment.

With such an efficient therapeutic agent as penicillin, one is justified in looking forward to the day when gonorrhea will be an extremely rare disease. There is much to be done, however, before that time will arrive. A male patient, who reported to us from another clinic and who had had his infection for thirty days, responded immediately to treatment clinically and bacteriologically. Subsequently, following a sex contact with his wife, he became reinfected. Cultures done on his wife were positive, whereupon she was treated with penicillin and the husband was re-treated, with the result that they are both now negative. It will be necessary to get all women now infected under treatment before the job can be completed, and this is something that will take time and perseverance.

There is a trend in military and civilian hospitals to have gonorrhea treated in medical rather than urologic or gynecologic departments. Turner and Sternberg² report as follows:

It can be said categorically, it is in those Army hospitals in which reliance is placed on internal medication and forced fluids to the exclusion of local treatment that the best results are being obtained. Nothing appears to be gained by urethral instillations, prostatic massage or the passing of sounds in the ordinary case of uncomplicated gonorrhea, and the proportion of complications appears to be significantly higher where these procedures are employed.

The Army's experience is similar to that of many clinicians: therefore, the medical department seems to be the logical place for treating gonorrhea.

wounds were infrequent, generally requiring closure of bowel perforations, rarely resection. There is no better criterion of the quality of the early surgery performed than to observe the later convalescence at the general hospital.

No complication of wound healing was more common than fungus diseases of the skin. Many kinds of pathogenic fungi exist in this humid jungle and constantly attack the combat soldier. Figures for tetanus and gas infection are not available.

Five factors played an important role in the care of the sick and wounded of this campaign. All were co-ordinated well, resulting in the saving of many soldiers. Without good surgery at a forward area, without plasma, without chemotherapy, without native carriers and without air evacuation, this could not have been accomplished.

Possibly I should have described the surgical care of the wounded in this campaign. The care of

the wounded soldier, however, involves more than the actual surgical care. The soldier, sailor or marine deserves the best. Perhaps it seems wise to illustrate the philosophy of the soldier by quoting excerpts from a letter written by a marine about to embark for overseas and found on his bed at the staging area after his departure: "Nurture strength of spirit to shield you in sudden misfortune . . . Try not to distress yourself with dark imaginings; many fears are born of fatigue and loneliness . . . And whether or not it is clear to you, no doubt the universe is unfolding as it should." That represents a creed, a faith, a trust and a purpose worth noting. Our soldiers are the best, and they look to the medical department of the Army or Navy for the best service. It is our obligation to determine that the medical service rendered is worthy of this marine's faith and trust. Speaking as one who has seen, it is a privilege to report that the wounded soldiers are receiving the best possible medical care.

MEDICAL PROGRESS

ANTIBIOTICS AND BACTERIOSTATICS IN BLOOD AND BODY FLUIDS

WILLIAM T. SALTER, M.D.*

NEW HAVEN, CONNECTICUT

IN the use of therapeutic agents of a chemical nature, it has become increasingly important to determine the concentration of the drug that circulates in the blood stream. For generations American chemotherapeutic agents have been thought of in terms of dosage, that is, the amount to be injected or ingested at a single administration. The modern concept more closely approaches the European meaning of the term "*dosage*," that is, the concentration of effective agent produced. It is becoming more and more essential to maintain the concentration of pharmacotherapeutic agents within certain limits.

If this is not done, two difficulties may ensue. If the concentration is too low, the drug will not be effective and fastness to the drug may ultimately develop. If, on the other hand, the concentration is too high, the danger of toxic symptoms and untoward side reactions becomes increasingly great. To steer through this Scylla and Charybdis must be the goal of the best therapy in the next decade.

In order to achieve this end, much more attention must be paid to methods whereby the approximate concentrations of circulating therapeutic agents can be determined easily and reliably. There are two general ways in which this can be done: first, the concentration may be determined directly in the cir-

culating blood, preferably in the serum or plasma; second, in certain cases the urine may be viewed as a blood filtrate, when due regard must be paid to the time interval represented by a given sample. Usually the latter procedure is feasible only if the agent is stable and no considerable storage depots exist in the organism.

Although the present article is concerned primarily with antibiotics and bacteriostatics, it should be pointed out that this principle of dosage — in the Continental sense — probably applies to a considerable number of chemotherapeutic agents. It is known, for example, that in the relief of hypothyroidism the ultimate aim is to raise the concentration of circulating "hormonal" iodine to a level approximating 5 microgm. per 100 cc.¹ Similarly, there is evidence that in the use of digitalis glucosides it is not highly satisfactory to know only the amount administered daily.² The desired therapeutic effect will be approached much more closely if one considers the concentration of glucosides circulating in the blood stream.³ Such facts raise the question whether dosage will ultimately be expressed in terms of milligrams or micrograms per 100 cc. of plasma rather than in amounts to be administered at a single moment.

This principle has become so evident in the case of the bacteriostatics and antibiotics, and the antibiotics are of such prime importance in the total war

*Professor of pharmacology, Yale University School of Medicine.

85,000 patients — a larger number than in any other theater.

Perhaps the most valuable development in military medicine in this theater concerning the care of the sick and wounded was the organization, development and operation of the portable surgical hospital. It is appropriate that credit be given to those particular units that pioneered in this early action. The general hospital, with which it was my privilege to serve, provided two such units, each commanded by a member of this society — Major Neil W. Swinton and Major George A. Marks. The portable hospital is a new development of this war, advisedly designated portable since the entire tentage, mess and surgical equipment and medical supply are carried on the backs of the personnel. Jungle warfare in a wet tropical atmosphere handicaps land transport to such an extent that the human pack is the only method of movement in the most advanced forward areas. Wards and operating rooms were tents, and beds were cots or litters elevated above the ground to avoid flooding. The personnel slept in "jungle beds." In the Buna Campaign selection of the site of the hospital was the really important requirement for reasonably comfortable operation of the hospital. Blackout requirements were enforced, and night operating was done with little or no ventilation. Because of the heat, the personnel were stripped to the waist.

Surgical care of the wounded was first carried out on the field of battle, where necessary dressings were applied; litters then bore the patient to the rear. Emergency care and necessary splinting were provided at the battalion aid station. From there, by litters or walking, depending on the location and type of the wound, the wounded were carried or directed to the portable surgical hospital, where major surgery or fracture reduction and splinting, where indicated, was accomplished. The patient was anesthetized, preferably with Sodium Pentothal but sometimes by spinal or local anesthesia. Blood plasma was used entirely as a substitute for whole blood, and saline and dextrose solutions for infusions. Fluid loss in perspiration was a constant factor in the tropics. The drugs used chiefly were the sulfonamides, quinine, tetanus toxoid and morphine. Nursing care was difficult in particular at night, when the only light was that from a hooded flashlight. Feeding patients hot food and caring for the usual sanitary requirements entailed by a bedpan were tedious and most trying tasks. The patients, however, received the best housing and the best medical and nursing care available within hundreds of miles, and remained in the hospital several days or until they could withstand the next stage of evacuation.

In reviewing the surgery later seen at the general hospital, one can but marvel at the results. One wonders why elaborate surroundings are required when such results can be obtained in the most prim-

itive environs. It was proved, however, that good and better surroundings were necessary for wound healing and more efficient bed care for eventual recovery. In other words, for only a few days did the patient gain in his primitive jungle surroundings.

The surgical procedures carried out have been described by Major Marks in a graphic account of his portable surgical hospital, published in the December, 1943, issue of the *Bulletin of the United States Army Medical Department*. At present he is acting as assistant to the surgical consultant in that theater, and doubtless will have more to describe when he returns. In his present assignment, he is putting to practical use his invaluable experience of this early campaign. Major Swinton, now commanding a field hospital at the advance base, will likewise have much to tell.

In considering the types of wounds and the surgery carried on, one should be cognizant of the weapons used by the enemy. Machine guns, small arms, grenades and mortars were the principal weapons employed by the Japanese. What artillery there was, was put out of action early in the engagement. Sniping was the favorite mode of fighting. Therefore, one would expect penetrating bullet wounds to be the most frequently encountered. Wounds of the soft parts were most frequent, many involving the peripheral nerves, bones and joints and about 70 per cent involving the extremities. Less frequently the head, chest and abdomen were hit. The booby trap, if it existed, was not mentioned by those evacuated to our general hospital. Any record of surgery under the circumstances described above should be judged in two phases — the immediate result and the condition of the wounds and fractures when the patient arrived at the general hospital. In both categories it is a pleasure to report a mortality of 3.6 per cent, including all wounded cases at the portable surgical hospital. This proved that excellent surgery had been done. The general hospital patient arrived in excellent surgical condition after over 1000 miles of travel.

Every surgical procedure carried out with the most modern concept of conservative débridement and fracture reduction and with sound judgment, proved to have been correct. The usual procedure for the surgical treatment of wounds consisted in dusting sulfonamide powder into the débrided wound and providing a gauze drain, and encasing the extremity in plaster of Paris slabs. Alignment of fractures at the time of débridement and application of plaster were essential, and only a few of these patients lost position in transit, this being corrected at the next hospital stay. Head wounds did not do so well if above the level of the mandible. Chest wounds were usually penetrating and through-and-through, accompanied by rib fracture and hemothorax and occasionally by infection. Abdominal

ount of the aliquot contained in the sample is 0.5 microgm. Apparently, other methods are used when the concentrations in blood or body fluids are lower than that just described.

Atabrine in blood and body fluids. One of the most useful of the methods suggested is that of Brodie and Udenfriend.⁹ In this procedure, atabrine is isolated from the biologic material being investigated by reaction of the free base at a pH of about 8.0 with ethylene dichloride. The solution is washed free of degradation products of atabrine with 2.5 N sodium hydroxide. The atabrine is then extracted with aqueous concentrated lactic acid. The final determination of the atabrine is performed in the lactic acid by means of its fluorescence.

A simpler method involves estimation of the atabrine through its fluorescence in the original ethylene dichloride solution. Incidentally, it should be remembered that this solvent may prove toxic. This last procedure is recommended for routine clinical use, and is extremely simple and rapid. In this way, even under field conditions, it is possible to know the concentrations of the drug circulating in the blood of each patient.

A similar method suggested by Masen¹⁰ is as follows:

Five cubic centimeters of oxalated blood is mixed with 5 cc. of 4 N sodium hydroxide and 8 cc. of an alcoholic mixture consisting of equal parts of isobutyl and isopropyl alcohol. One cubic centimeter of water and 7 cc. of petroleum ether (B.P. 30-60°C.) are added. Next, 1 cc. of the atabrine standard, containing 63.6 mg. per liter, is added to another 5-cc. sample of the same blood. It is treated similarly and is shaken for five minutes.

The upper alcoholic layer containing the atabrine is removed. Preliminary centrifugation may be needed to break emulsions at this stage. To the upper layer is added 10 cc. of a solution containing 30 per cent isopropyl alcohol in 10 N hydrochloric acid. The lower layer from this combination is saved, and an 8-cc. sample is taken. This is stabilized with 1 cc. of a buffer consisting of 4 gm. of sodium borate in 100 cc. of 1.35 N sodium hydroxide. The final comparison between standard and unknown is made in a fluorometer, according to the following equation:

$$\text{Conc. of unknown (mg. per liter)} = \frac{U}{S} \times \text{standard conc.} \times 200.$$

U being the reading of the unknown and *S*, that of the standard

The fluorometric method for estimating atabrine has been extended by Auerbach and Eckert¹¹ by the use of caffeine sodium benzoate. In the presence of this reagent the fluorescence of atabrine is intensified some fifteen times. With this procedure a 5-cc. sample of blood containing 0.1 microgm. of atabrine yields a significant result. Furthermore, the sensitivity is adequate for the analysis of blood concentrations such as are found under actual therapeutic conditions. A preliminary extraction with ether is required. For best results the temperature must be controlled.

This procedure has been applied to human blood and bloods from the following animals: rabbit, rat, pig and duck. At a concentration of about 4.0 microgm. per 100 cc. of whole blood, the recovery is 96 per cent or better, and the manipulation involved is simple.

Atabrine in urine. It is well recognized that after the administration of atabrine, the urine contains material that emits an intense yellow color and fluorescence. It has been assumed by some workers that this appearance of the urine is entirely due to unchanged atabrine, and this material *in toto* has been determined as a means of measuring the saturation of atabrine in the blood and body tissues. The work of Scudi and Jelinek,¹² however, has shown that a number of acridine derivatives appear in the urine following administration of the drug to experimental animals. The partition of these various acridines varies from species to species, and is different in laboratory animals from what it is in man. Consequently, any method that is to be applied clinically must take cognizance of the fact that the urinary excretion of atabrine is quite complex.¹³ If the excretion products found in the urine were active against malaria, there might not be any objection to treating them as atabrine. Experiments by Seeler,¹⁴ however, have shown that at least one of these fractions is not active against the schizonts of avian malaria at dosages of 20 to 100 mg. per kilogram. Moreover, these concentrates were more toxic than is atabrine.

The method of Brodie and Udenfriend⁹ has the advantage that any decomposition products of atabrine that may also be present are not recorded. In this respect the method is preferable to somewhat simpler methods, such as that of Craig,¹⁵ which also depends on fluorescent material. The use of fluorescence to detect the atabrine endows the procedure with a high degree of specificity. A Coleman glass filter No. B₂, combining both Corning No. 5113 (2 mm.) and No. 3389 (2 mm.), is used to limit the transmission of fluorescent light, and is more specific than Corning No. 5113 alone, which permits greater sensitivity but transmits a considerable amount of fluorescence derived from normal components of biologic materials.

QUININE IN BLOOD, BODY FLUIDS AND URINE

Now that many observers have decided that quinine is not the drug of choice in many cases of malaria, information regarding its pharmacologic fate is being released for general perusal. Intensive work on its behavior in animals and man has been accumulating behind closed doors during the last three years, and some of it — especially work on the related isomer quinidine — will be of permanent and practical interest. Of this large and rapidly appearing literature, only a few significant instances can be cited.

Quinine in blood and body fluids. In 1931, Vedder and Masen¹⁶ demonstrated that the effectiveness of antimalarial therapy depends on the maintenance of certain concentrations of the drug in the circulation. Because the drug disappears rapidly from the blood after intravenous injection,^{17, 18} it is desirable to follow the blood level to ascertain the need for

effort, that it seems desirable to summarize a few of the methods now available for clinical use. At present most of these are limited to large clinics, but there are indications that further simplifications will make them available even to the busy practicing physician so that he may carry on intelligent therapy. Indeed, it seems likely that many of the untoward effects that are reported through widespread use of the sulfonamides could be avoided if the amount of circulating drug were better known in the given case. To many local practitioners this may seem too much to expect, but probably the procedures involved will eventually be no more complicated than are many methods ordinarily used in clinical pathology.

SULFONAMIDE COMPOUNDS IN THE BLOOD, BODY FLUIDS AND URINE

The distribution of sulfonamide drugs in body fluids has been discussed recently in this journal by Davis,⁴ who has discussed the possible mechanisms of their action.

The original method of Marshall⁵ has proved to be so useful in the control of sulfonamide therapy that various modifications and improvements are important. One such advance has been suggested by Scudi and Jelinek.⁶ This latest modification allows the color to be concentrated so that it is possible to measure highly diluted blood filtrates. Because the heterocyclic sulfonamides tend to be adsorbed by protein precipitates, it is especially desirable that protein be precipitated in dilute solution. The device suggested by Scudi and Jelinek consists in extracting the final color produced by the azo-dye reagent with small volumes of butyl alcohol. The method is easily applicable to routine blood analyses.

These authors worked with solutions of sulfanilamide, sulfathiazole and sulfapyridine at concentrations ranging from 0.1 to 0.5 mg. per 100 cc. After the production of the color in the usual manner, they extracted this dye with *n*-butanol. In this way they were able to concentrate the dye and so to increase the intensity of the color produced for a given amount of the bacteriostatic concerned. In the case of sulfanilamide itself, only 90 per cent of the dye was extracted, but in the case of the heterocyclic sulfonamides, production of the color was complete.

This refinement will be useful in studying bacteriostatics that are effective at low concentrations and in studying the distribution of bacteriostatics throughout various body fluids. The principle may also be used in preparing standards for direct visual comparison, as in clinical tests.

In applying this method to various primary aryl amines, it is necessary in each case to use the pure compound in question in the standard. The use of a green filter (Corning, Sextant 63, No. 401, 2 mm. thick) is desirable, especially with weak colors. The routine procedure for oxalated blood as extensively practiced in clinical laboratories calls for 2 cc. of blood. The classic procedure, in brief, is as follows:

Exactly 2 cc. of oxalated blood is delivered into a flask and laked with 30 cc. of saponin solution. After standing for two minutes the blood proteins are precipitated with 8 cc. of 15 per cent trichloroacetic acid in aqueous solution, and the precipitate is filtered off. Ten cubic centimeters of the filtrate is taken for determination of the free drug. To this sample 1 cc. of 0.1 per cent sodium nitrite is added, and the combined solution is allowed to stand for three minutes at 0° C. or at some known temperature. Next, 1 cc. of a 0.5 per cent ammonium sulfamate solution is added to exhaust the excess of nitrite. After two minutes, 1 cc. of the solution of *N*-(1-naphthyl) ethylenediamine dihydrochloride is added. The color develops rapidly.

The newer method of Bratton and Marshall,^{7,8} which employs *N*-(1-naphthyl) ethylenediamine dihydrochloride, has now been adapted to the following sulfonamide derivatives: sulfanilamide, sulfapyridine, sulfathiazole, sulfaguanidine and sulfadiazine. For use with sulfamerazine and other compounds, certain modifications are necessary, but these are not yet standardized. The unknown is compared with an appropriate standard that has been treated as described above. It is convenient to set the 1-mg. (per 100 cc.) standard at 10 mm., the 0.5-mg. standard at 15 mm., and the 0.2-mg. standard at 20 mm. depth in the Duboscq colorimeter. This comparison can be made immediately, and if solutions are kept in the dark, no change in color is observed for an hour or more. To determine the total drug, 10 cc. of the filtrate is treated with 0.5 cc. of 4 N hydrochloric acid, heated in a boiling water bath for one hour and cooled, and the volume is adjusted to 10 cc. The subsequent procedure is as stated above for determining the free drug.

If the urine is used as a rough indication of blood concentration, it should be acidified and diluted so that the final concentration is 1 or 2 mg. per 100 cc. The diluted urine can then be compared with the usual standard solutions for blood, as described by Bratton and Marshall.

ATABRINE* IN BLOOD, BODY FLUIDS AND URINE

The present restrictions on methodology in the use of antimalarials — restrictions that apply even to the simplest of almost self-evident facts — prevent any detailed discussion of the aims that are to be desired in the use of atabrine, either in the suppression or the treatment of malaria. One can only quote material published in the general literature, such as the following:

Information on the plasma concentrations of atabrine in either of the latter conditions should prove as helpful in the quantitative control of such therapy as is information on the plasma concentration of the sulfonamides in the control of sulfonamide therapy.⁹

One is not allowed to divulge the concentrations required to produce effective therapy or suppression, but one does note from the published literature that the available methods are applicable when the concentration is at least 50 microgm. per liter and the

*Although the term "atabrine" has been superseded in the *United States Pharmacopoeia XII* by the term "quinacrine hydrochloride," the older term has been retained in this article because of its general contemporary use.

One of the most convenient of these newer procedures is that of Sherwood, Falco and de Beer.²⁷ The authors have informed me that it should prove satisfactory for blood provided the standard dilutions of penicillin (used for comparison) also contain an equivalent amount of blood. In this method, 5 cc. of nutrient agar (pH 7.0) containing 200,000 *Bacillus subtilis* spores per cubic centimeter is poured into a Petri dish, and after the agar has solidified, four sterile filter-paper disks (15.3 millimeters in diameter) are spaced evenly upon its surface. These disks are used to absorb and retain the samples under test. Four plates are employed, each testing simultaneously two dilutions of the standard (S) and two of the unknown (U). The weaker of both dilutions should be one fourth, as concentrated as the stronger. Each of these four samples is placed on one of the paper disks and allowed to soak into it. In taking small samples of the four liquids, it was found that a bacteriologic drop was nearly as accurate as a micropipette. The drop had the advantage that it was more readily cleaned and prepared for use. After some five hours of incubation at 37°C., the colonies of *B. subtilis* should have grown sufficiently to delineate clear zones of inhibition. The diameter of this zone should be measured to the nearest millimeter, and the sums of the four zones of inhibition produced by the standard (S₁) and weak standard (S₂) and by the unknown (U₁) and weak unknown (U₂) should be ascertained by addition.

The potency of the unknown (U) with reference to the standard (S) can be calculated from the following equation,

$$\text{Potency} = \text{antilog} \left\{ 2 + d \frac{(U_2 + U_1) - (S_2 + S_1)}{(U_2 - U_1) + (S_2 - S_1)} \right\}.$$

In this equation, *d* signifies the log of the ratio of the greater dose to the smaller dose. This type of assay is statistically sound and convenient. It deserves a careful trial with blood and other body fluids.

In applying this method, it is necessary to control a number of variables that affect the answer. Among these are the temperature and duration of incubation, the size of the disk, the depth of the agar, the volume of the dose and the number of *B. subtilis* spores per plate. If these factors are maintained constant, however, the results are satisfactory for most biologic problems.

Recently Goth and Bush²⁸ have suggested a rapid method for the estimation of penicillin. This is based on the finding that the antibiotic inhibits the production of nitrite from nitrate by cultures of *Staphylococcus aureus*. This test can be carried out in less than ninety minutes. Furthermore, its accuracy is greater than that of the serial dilution method commonly used.

The test strain of *Staphylococcus aureus* is grown for twenty-four hours in a special peptone medium and then diluted with a medium containing peptone,

sodium nitrate and *p*-aminobenzoic acid. A standard preparation of penicillin is used as a control tube and treated in the same fashion as the unknown. After sixty to ninety minutes' incubation the concentration of nitrite is determined.

The determination of the nitrite formed is based on the method of Shinn.²⁹ A trichloroacetic acid filtrate is treated with *N*-(1-naphthyl)ethylenediamine dihydrochloride. The resulting color is determined after three minutes in a photoelectric colorimeter with a green filter (Cenco No. 525P). Because an excess of *p*-aminobenzoic acid is present, the intensity of the color developed in this diazotization process is determined by the concentration of the nitrite present. Appropriate standard solutions containing known concentrations of nitrate are used as the basis for comparing the control tube with the unknown. Obviously, it is essential that all cultures be incubated for the same time at the same temperature.

Rammelkamp³⁰ has also described a simple method for determining the concentration of penicillin in body fluids and exudates. Because hemolytic streptococci are four to sixteen times as sensitive as staphylococci, an especially sensitive Group A strain of hemolytic streptococcus isolated from a case of erysipelas was chosen. Broth cultures at twelve hours (in veal infusion with 1 per cent erythrocytes) were diluted so that the number of organisms per cubic centimeter ranged from one thousand to ten thousand. Half a cubic centimeter of this dilution was added to each unknown sample, comprising 0.7 cc. total volume. The test tubes were then incubated for eighteen hours and finally examined for hemolysis. By comparing such a series with a series containing known amounts of penicillin, one can estimate amounts as low as 0.0039 Florey unit per 0.2 cc. of solution.

This method is applicable to urine, whole blood, erythrocytes, joint fluid, spinal fluid and exudates from empyema cavities. Unknown samples may be stored at 5°C. for two weeks before testing without serious loss, unless contaminated. In such a case it is wise to sterilize the sample by passage through a Berkefeld or Seitz filter.

Effective concentration. Rammelkamp and Keefer³⁶ studied the concentrations of penicillin in the blood stream required to produce optimal effects. For *Streptococcus haemolyticus* the value was between 0.019 and 0.156 unit per cubic centimeter of serum, whereas for maximum bacteriostatic effect with *Staph. aureus*, at least 0.156 unit was required. Furthermore, whole blood containing 5.1 mg. of sulfadiazine per 100 cc. was less active against streptococci than was whole blood containing 0.7 unit of penicillin per 100 cc. After intravenous (or intramuscular) injection of penicillin large amounts of the drug appear in the urine, even as much as half the injected material. Unfortunately, intravenous injection is not followed by elimination of penicillin

further dosage or to regulate the program of medication. Until recently highly specific methods were available, but these generally involved a time-consuming extraction process. Brodie and Udenfriend,¹⁹ however, have described a simple but precise method probably applicable to human plasma.

The test is based on the strong fluorescence of acid solutions of the alkaloid in ultraviolet light. When the quinine concentration is low, the intensity of emitted light is proportional to the alkaloidal concentration. The absolute concentration is, in fact, too low because of so-called "quenching," but this fault is automatically corrected by using appropriate control standard solutions. In order to avoid serious loss of the drug by adsorption on the protein precipitate, the plasma filtrates are prepared at high dilution by the use of metaphosphoric acid. The final concentration is read in a photofluorometer over the range of 1 to 30 microgm. per 100 cc. Above plasma concentrations of 100 microgm., the method gives very satisfactory results. Moreover, because the filtrates are stable, they can be stored for several days and analyzed in groups. The method is also adaptable to quinidine.

In connection with experimental work on avian malaria, Kelsey, Oldham and Geiling²⁰ have studied the distribution of quinine in the tissues as well as in the blood of fowls after oral administration. These results were compared with the effect of intravenous injection. An interesting finding was a temporary accumulation of quinine in the red cells at a concentration higher than that in plasma. The leukocytes show an even more striking preferential accumulation. The blood rapidly yields up its initial load of drug, so that ten minutes after intravenous injection high concentrations are found in the liver, kidneys, spleen, adrenal glands, lungs and liver. The data serve to emphasize the important fact that quinine is not accumulated in the tissues even after long-continued administration. Quantitatively, the results confirm those in the dog and cat reported by Hatcher and Weiss.²¹

Quinine in urine. The medical services of the armed forces have been obliged to develop simple tests for the detection and rough estimation of quinine in the urine. Such tests are needed to detect those who have failed to take prophylactic medication. They may also be used in a semiquantitative fashion to control suppressive dosage. Independent studies by Cornell and Kaye²² and by Glazko²³ have shown that the double iodide of mercury (HgI_2K_2) can be used directly in urine without preliminary extraction. The precipitate of iodo-mercurate dissolves on boiling, whereas albuminous precipitates do not. If precise results are needed, the turbidity produced can be measured with a photonephelometer. In this case the acidity and the range of concentration of the quinine must be adjusted for best results to pH 2.0 and 1 to 5 mg. per 100 cc., respectively. When 0.6 gm. of quinine sulfate was ingested, it was

found by this method that the urinary quinine excretion rose at four hours to a peak of nearly 25 mg. an hour, and gradually declined to less than 5 mg. after fourteen hours.

Although urinary quinine excretion is variable, approximately 40 per cent of the usual therapeutic dosage is excreted by this route. The excretion is rapid, and after twenty-four hours only a trace appears in the urine.

The excretion of quinine is influenced by several variables, among which the urinary acidity is important. Haag, Larson and Schwartz,²⁴ for example, gave 0.5 gm. of quinine orally to human subjects and found that when the urine was maintained alkaline, half as much quinine was excreted as with an acid urine. At best, however, the resulting conservation of the drug seemed to be less than 10 per cent.

PENICILLIN IN BLOOD AND BODY FLUIDS

In the use of penicillin it is especially advantageous to determine the concentration of circulating antibiotic, particularly in cases being used for statistical studies of the therapeutic results. Penicillin is so rapidly removed from the blood stream and so largely excreted in the urine that an interval of two hours reduces the effective concentration to very low limits.

Some 58 per cent of penicillin is excreted by the kidneys after intravenous injection.²⁵ Rammelkamp and Keefer²⁶ found that this loss occurs largely in the first hour after injection. The effect of Diodrast in preventing the excretion was striking. Whereas about 57 per cent of intravenous penicillin was lost in the course of a few hours, with Diodrast only 32 per cent was recovered in the urine. Despite this conservation of penicillin, however, the blood level became negligible in less than two hours. Without Diodrast, it reached zero in approximately forty-five minutes.

The hemolytic streptococcus is extremely sensitive to penicillin, but even in this instance a concentration of at least 0.15 units per cc. is desirable. Various procedures and various derivatives are being tested in the hope of maintaining a high concentration over a longer period. At present the drug must be administered every two hours in order to hold the blood concentration up to effective levels.

The methods now available for the estimation of penicillin activity are essentially bioassay procedures. Accordingly they involve the usual *bête noire* of biologic variation. This fact implies that for greatest accuracy the answer, in graphic terms, should be read as a *line* rather than as a single point or single value. The new methods for the assay of penicillin take cognizance of this statistical situation, and provide for a matching of the unknown with known standards. Unfortunately no extensive published experience is yet available with this type of procedure as applied to blood.

CASE RECORDS OF THE MASSACHUSETTS GENERAL HOSPITAL

Weekly Clinicopathological Exercises

BENJAMIN CASTLEMAN, M.D., *Acting Editor*

EDITH E. PARRIS, *Assistant Editor*

CASE 30451

PRESENTATION OF CASE

First admission. A seven-year-old Negro school-child entered the hospital because of exophthalmos. The child had been in apparent good health until fifteen months before entry, when she seemed to become restless, nervous, irritable and emotional. A month or two later exophthalmos was noted. During the next few months the symptoms progressed, becoming more marked after an attack of measles. She failed to gain weight, although there was an increase in height of 2 inches in six months. About one month before entry, during an examination in a community hospital, a lump was found in her neck and the basal metabolic rate was noted to be +65 per cent.

The patient had had whooping cough at four years of age and chicken pox shortly afterward. There was a question of head injury at fifteen months of age but x-ray films of the skull taken at a community hospital at that time were negative.

Physical examination showed a well-developed and well-nourished girl. There was slight tremor of the tongue. The thyroid gland was symmetrically and uniformly enlarged. No thrills were palpable over the gland, but a bruit could be heard. Exophthalmos was present, and the hands showed a moderately coarse tremor. There was a loud systolic murmur, best heard at the apex but audible over the entire precordium.

The blood pressure was 120 systolic, 60 diastolic. The temperature was 99°F., the pulse 120, and the respirations 25.

Examination of the blood showed a red-cell count of 5,100,000, with 85 per cent hemoglobin. The white-cell count was 7500, with 74 per cent neutrophils. The urine was normal, with a specific gravity of 1.026. The basal metabolic rate was +63 per cent. The serum cholesterol was 127 mg. per 100 cc. A blood Hinton test was negative.

The patient was given 1 drop of a saturated solution of potassium iodide three times a day, and on the twentieth hospital day a right hemithyroidectomy was performed. The weight of the specimen was 8.2 gm., and on microscopic examination it showed hyperplasia. The patient withstood the

operation well, but on the first and third post-operative days there was considerable oozing of blood from the incision and she was given several transfusions. On the fourteenth hospital day the basal metabolic rate was +15 per cent for height and +32 per cent for weight, with a pulse of 96. The patient was discharged on 5 drops of potassium iodide twice a day and was told to return in six weeks for the removal of the remaining lobe of the thyroid gland.

Second admission (six weeks later). Following discharge the patient remained well, gained 10 pounds and was less nervous.

Physical examination was the same as before.

The temperature and respirations were normal, and the pulse was 96. The basal metabolic rate was +43 per cent for height and +54 per cent for weight.

On the second hospital day a left hemithyroidectomy was performed with the removal of 15 gm. of histologically hyperplastic thyroid tissue. Again there was considerable postoperative bleeding. The basal metabolic rate fell to +5 per cent, and the pulse to 78, and she was discharged on the tenth hospital day.

Final admission (eight years later). Following discharge the patient did well for about two years, at the end of which time definite thyroid tissue was again palpable in the neck and seemed to be increasing in size. The basal metabolic rate was +16 per cent for height and +30 per cent for weight, and the pulse was 120. She was placed on 5 drops of a saturated solution of potassium iodide three times a day. During the next two years, tremor and nervousness reappeared, the mass in the region of the thyroid gland definitely enlarged and the basal metabolic rate rose to +23 per cent for height and +34 per cent for weight. At that time she was given 150 r of x-ray therapy for two doses, followed by two doses of 200 r each. During the month after x-ray therapy the basal metabolic rate gradually fell to -17 per cent for height and -13 per cent for weight; the pulse was 66. She then developed a rash and the potassium iodide therapy was discontinued. The thyroid nodule decreased in size and her condition seemed much improved. The patient apparently remained well until three weeks before the final entry, at which time her appetite became poor and she developed polyuria and polydipsia, and began to lose weight. Ten days before entry she appeared tired, "peppless" and sleepy and complained of pain and tenderness in the costovertebral angles. One week prior to admission there was itching of the genitalia and anus, followed by the draining of a perianal "abscess" three days later. Two short episodes of epistaxis occurred spontaneously. The night before entry the patient became drowsy, with frequent attacks of vomiting, and the next morning was difficult to rouse.

*On leave of absence.

into the spinal fluid. It has been assumed that for this reason penicillin administered intravenously is useless in the treatment of meningitis.

Recent work by Rosenberg and Sylvester,³¹ however, has indicated that the blood-brain barrier is altered in cases of meningitis. These investigators injected 8 patients with meningitis intravenously or intramuscularly, in doses ranging from 20,000 to 40,000 Oxford units. One or two hours later penicillin appeared in the spinal fluid in concentrations of 0.03 to 0.35 unit per cubic centimeter. Because the magnitude of this concentration is adequate for blood, the possibility exists that such cases can be treated without intrathecal injection. Further data are needed. Such observations should, of course, be made only under carefully controlled circumstances, but they appear to show that observations in normal subjects do not reflect the situation when inflammation is present.

Various devices are now under test in an effort to maintain effective concentrations of penicillin for longer periods. Some of these involve a modification of the preparation of penicillin, but these experiments are still in the initial stages so far as information is available at present. Another interesting approach, however, has been the depression of renal excretion by agents that are relatively innocuous to the kidney. For example, Rammelkamp and Bradley²⁵ found that the excretion of penicillin by the kidney was inhibited after the injection of Diodrast.

Recently Beyer and his associates³² have investigated a similar use of *p*-aminohippuric acid, which is secreted by the tubular epithelium, as shown by Smith and his associates³³ and by Bing.³⁴ Experiments in dogs conducted by Beyer and his associates showed that when the plasma level of the hippuric acid derivative is maintained at between 20 and 30 mg. per 100 cc., penicillin is retained in the blood at effective concentrations for appreciably longer periods. Thus, in the control experiments after a single injection of 10,000 Oxford units, the antibiotic was no longer detectable in the plasma after two and a half hours. In animals treated with the hippuric acid derivative, however, detectable concentrations of penicillin persisted in the plasma for three and a half hours. Simultaneously the renal clearance of penicillin from the blood and its recovery in the urine were decreased. Toxicologic studies have shown in mice, rabbits and dogs that *p*-aminohippuric acid is remarkably nontoxic, so that a cautious trial of its use with penicillin is desirable in view of the higher concentrations possible and the increased economy of therapy.

The methodologic aspect of controlled chemotherapy has been stressed in this survey because it is too often neglected. Any clinical report is of little scientific value if it claims that penicillin is ineffective without giving evidence that the concentration in the circulating blood has been maintained adequately high and for an adequately long period. At this stage of knowledge regarding penicillin and other antibiotics, the necessity for constant control

of concentration in the blood cannot be emphasized too strongly.

SUMMARY

If the antibiotics and bacteriostatic agents now available are to be used effectively, their circulating concentration must be known and controlled. Simple methods are now available that can be applied to blood, urine and body fluids. Unless such a check is used in critical cases, it is unwarranted to conclude that the therapeutic agent under test is ineffective. This precautionary procedure is also necessary in most cases to guard against toxicity due to overdosage.

34. Bing, R. J. Etiology of renal failure following

BUTLER: One can have local irritation from glycosuria. I have never seen perianal in children with diabetes. I do not know or not they occur in adults.

Epistaxis makes one wonder whether there is generalized infection, hypertension or rheumatism. I do not recall epistaxis in diabetes, in diabetes mellitus or in Addison's disease. Tenderness in the costovertebral angle was again elicited on physical examination. I should know how well or poorly this patient was doing.

COTZIAS: She was well nourished.

BUTLER: The draining perianal abscesses on the apparently were not superficial, since pus was obtained on incision. One wonders whether a skin test was done.

COTZIAS: Not during the time that we were here.

BUTLER: There was no evidence of infection. Are there any abscesses in the perianal region. Are there any other records of blood pressure? Is there any evidence that she had a hypertension during the dehydration.

COTZIAS: I do not recall.

BUTLER: If a person with diabetes mellitus ingests food, the resulting starvation leads to overproduction of ketone bodies and acidosis develops rapidly. If such a person then begins to drink the combination of glycosuria, ketosis and dehydration fluid by vomiting quickly produces dehydration. In the presence of such dehydration the hands and feet are usually cold, the circulation is poor and the temperature not elevated, but the temperature subsequently becomes elevated as the patient is rehydrated. Hence, the temperature of 102°F. on admission suggests infection. The pulse was 140. One wonders whether the pulse was poor and rapid.

COTZIAS: The pulse was poor.

BUTLER: That probably reflected the dehydration, possibly an overwhelming infection. The leukocytes were 45 and Kussmaul in character. Examination of the blood showed a red-cell count of 5,140,000, with 15 gm. of hemoglobin. "Dehydration may produce a normal red-cell count when actually there is anemia. The white-cell count was 35,000. That is high but not impossibly high for just dehydration. It does, however, make me think of infection.

Examine the urine examination was done on a random specimen. We have to assume that there is no albuminuria and that it was not just from contamination of a voided specimen. The leukocytes may reflect a cystitis. The blood sugar was 500 mg. per 100 cc., which is average for diabetic coma. I take it that no casts were seen, and that is against nephritis.

Positive story, positive physical findings, and positive blood sugar and positive tests for urine

sugar, diacetic acid and acetone in a dehydrated patient indicate diabetic acidosis. Kussmaul breathing confirms the suggested metabolic acidosis.¹ It tells one that the blood carbon dioxide content is low. I suggest that a whole blood or serum carbon dioxide determination in such a patient is relatively uninformative.¹

Suppose this child had salicylate poisoning instead of diabetes mellitus and diabetic coma. Then the hyperventilation would have been due to the toxic action of the salicylates on the respiratory center; the carbon dioxide content would still have been low, — perhaps not this low, — but the patient would have had an alkalosis, not an acidosis.¹ So the carbon dioxide determination does not even tell whether the patient had acidosis or alkalosis, unless one has used one's common sense as regards the history and physical findings. When one has done so, a carbon dioxide determination contributes practically nothing. Even in a quantitative sense it adds little of clinical importance, since the Kussmaul breathing indicates the extent of the acidosis.

So I should not have asked for a carbon dioxide determination. But I should have asked for a non-protein nitrogen test, since this child possibly had renal disease, and I think that her care in the next twenty-four hours would have been facilitated if it was known whether or not she had renal disease. A high nonprotein nitrogen level on admission might merely have been due to the dehydration. But after the child was hydrated and a good urine volume was obtained, a second test would have shown the part that renal disease played in the picture. I should also rather have had a serum protein than a serum carbon dioxide, because the patient was sure to be given a lot of parenteral fluids. The concentration of the serum protein would have provided information concerning the patient's nutritional state and her ability to handle parenteral fluids. If the serum protein was elevated, fluids could have been given parenterally without danger of edema unless there was a lot of infection. If the serum protein concentration was not elevated in the state of dehydration, one could have been sure that it would be lower after hydration and hence would have been careful about edema as parenteral fluids were given.

I am going to pass over the insulin therapy. I do not believe that the amount of insulin given is really the important factor. One should give enough and not too much. The main thing is the manner in which this patient was supplied with the immediate metabolic needs of fluid and with other substances, including insulin. In the first two hours of therapy the blood sugar fell from 500 to 330 mg., and the acetone was somewhat less, perhaps because all the urine analyses were qualitative — not only in terms of chemistry but in terms of urine volume. I am sure that when the tests for acetone and sugar were done no account

Physical examination showed a semicomatose, dehydrated girl with typical Kussmaul respirations at a rate of 45. Considerable tenderness was present in both costovertebral angles. A draining abscess was present on each side of the anus; both, however, appeared to be quite superficial. Examination was otherwise negative.

The blood pressure was 130 systolic, 70 diastolic. The temperature was 102°F., the pulse 140, and the respirations 45.

Examination of the blood showed a red-cell count of 5,140,000, with 15 gm. of hemoglobin. The white-cell count was 35,500, with 84 per cent neutrophils. Examination of the urine showed a specific gravity of 1.020, a reaction of pH 6, a + test for albumin, a red test for sugar, a +++ test for diacetic acid and a +++ test for acetone; the sediment contained 10 to 15 red cells and 50, to 60 white cells per high-power field. The blood sugar was 500 mg. per 100 cc., and the carbon dioxide combining power 5.7 millimols per liter.

Over the next two hours the patient was given 150 units of insulin subcutaneously and 300 units intravenously in divided doses, with the result that the blood sugar dropped from 500 to 330 mg., the test for sugar in the urine changed from red to brown and the acetone became noticeably less (+++). Over the next four hours the test for sugar in the urine changed to green, with a + test for acetone. Only 80 units of insulin were given subcutaneously over that period of time. During the first six hours she received intravenously 4500 cc. of a solution consisting of two-thirds isotonic saline solution and one third 1/6 molar sodium lactate solution, as well as 250 cc. of plasma. At the end of that period the urine showed only a faint test for acetone and a negative test for sugar. She was more responsive, and the respirations were 35 and approximately normal in depth. The measured urine output during that period was 1560 cc., but it actually was greater since a considerable amount leaked around the catheter.

On admission 1000 cc. of clear fluid had been aspirated from the stomach; the tube was left in place, and the viscus was kept empty by frequent aspirations. At the end of five hours 25 cc. of broth was introduced through the tube into the stomach; this was repeated at half-hour intervals and was well tolerated. The perirectal abscesses were opened, about 20 cc. of pus being obtained. The patient was then given 1000 cc. of 10 per cent dextrose in isotonic saline solution, along with 40 units of insulin, over one and a half hours. The test for urine sugar, however, was brown, and that for acetone +++. At that point the patient became less responsive and the respirations assumed a peculiar gasping quality. Isotonic saline solution containing 2.5 gm. of sodium sulfadiazine was given intravenously because of persistent leukocytosis and a fever of 101°F.; the

volume was 2000 cc. over the next five hours making a total of 6850 cc. of parenteral fluids. The urine output continued to be approximately 200 cc. per hour. The insulin dosage was between 30 and 60 units an hour from the eighth to the twelfth hour of hospital stay, at which time the test for urine sugar became negative. Subsequently only small doses of insulin were introduced, the total dosage of regular insulin being 810 units. The patient became acetone free from the tenth hour on.

Gasping respirations continued, however, and the patient remained semiresponsive. The blood pressure was constant at 130 systolic, 70 diastolic, except for occasional transient rises to 150 systolic, 70 diastolic; one and a half hours before death it rose to 160 systolic, 100 diastolic. The pulse never dropped below 120. At no time was peripheral or pulmonary edema evident. The white-cell count varied from 27,000 to 29,000. Sixteen hours after entry the patient suddenly became unresponsive, and expired fifteen minutes later.

DIFFERENTIAL DIAGNOSIS

DR. ALLAN M. BUTLER: This is an example of hyperthyroidism in childhood, which is frequently extremely serious. Because hyperthyroidism in childhood is so rare, and since most pediatricians know so little about the condition, when they encounter a case of hyperthyroidism they had better send it to a physician for adults who knows hyperthyroidism rather than attempt to treat the case themselves.

I shall start discussing this case at the third admission, eight years after the original admission. The patient was then fifteen years of age. At that time she again had a recurrence of the symptoms of hyperthyroidism in spite of two subtotal thyroidectomies. The decision was made to irradiate the thyroid gland, following which the manifestations of the hyperthyroidism disappeared. Since we are not told much else about the child's thyroid condition, I assume that there were no further symptoms of hypothyroidism.

The development of polydipsia, polyuria, loss of weight and change in appetite usually means one of three things — renal disease, diabetes mellitus or diabetes insipidus, with or without brain tumor. It may possibly mean Addison's disease.

I should like to know whether the child was constipated.

DR. GEORGE C. COTZIAS: She was not constipated.

DR. BUTLER: Usually with dehydration resulting from untreated diabetes, the patient becomes constipated. Abdominal pain, probably due to the dry, impacted feces that result from dehydration and constipation, is not uncommon. But this patient was not constipated, and the pain and tenderness were in the costovertebral angle according to the record — not in the abdomen. Is that correct?

DR. COTZIAS: Yes.
